The Brier Score measures the mean squared difference between predicted probabilities and actual outcomes as expressed in Eq. (17), where N denotes the total number of observations, $\hat{p}_i$ represents the predicted probability, and y_i denotes the actual class label.

$$Brier = \frac{1}{N}\sum_{i=1}^{N}(\hat{p}_i - y_i)^2 \quad (17)$$

ECE measures the difference between prediction confidence and observed accuracy. Dividing predicted probabilities into M confidence bins, ECE is defined as given in Eq. (18), where B_m denotes the set of samples belonging to the m-th confidence bin, $acc(B_m)$ represents the empirical accuracy within bin B_m, and $conf(B_m)$ represents the average confidence within bin B_m.

$$ECE = \sum_{m=1}^{M}\frac{|B_m|}{N}\ |acc(B_m) - conf(B_m)| \quad (18)$$

A lower ECE indicates better calibration and closer alignment between predicted confidence and actual outcomes. To complement these numerical metrics, reliability diagrams

visually evaluate calibration by plotting observed accuracy against predicted confidence across multiple intervals.

3) Statistical significance analysis: The Wilcoxon signed-rank test was used to determine whether performance differences between ensemble methods are statistically significant. This non-parametric test compares paired results across walk-forward folds without assuming a normal distribution.

The null and alternative hypotheses are: H_0 (there is no statistically significant difference between the compared methods, and H_1 (there is a statistically significant difference between the compared methods).

All tests used a significance level of $\alpha = 0.05$. We compared CAEV-C against Hard Voting and Soft Voting baselines across accuracy, F1-score, ROC-AUC, and ECE to verify whether performance gains reflect consistent improvements across evaluation folds rather than random variation.

V. Results and Discussion

A. Performance of Base Models

Before evaluating ensemble aggregation, the three baseline models (XGBoost, LightGBM, and BiLSTM) were tested independently across all stocks and walk-forward folds. The evaluation covers both classification and calibration metrics. Table V summarizes the aggregated test results for each model.

TABLE V. Overall Performance of Individual Prediction Models

Metric	XGBoost	LightGBM	BiLSTM
Accuracy	0.4992 ± 0.0327	0.5033 ± 0.0380	0.4917 ± 0.0331
Precision	0.5497 ± 0.0911	0.5522 ± 0.0925	0.5294 ± 0.0620
Recall	0.4291 ± 0.2241	0.4350 ± 0.2332	0.4227 ± 0.2391
F1-Score	0.4393 ± 0.1510	0.4399 ± 0.1687	0.4244 ± 0.1720
ROC-AUC	0.5185 ± 0.0297	0.5259 ± 0.0299	0.5097 ± 0.0399
Brier Score	0.3404 ± 0.0449	0.3012 ± 0.0357	0.3377 ± 0.0394
ECE	0.2777 ± 0.0664	0.2053 ± 0.0680	0.2701 ± 0.0668

As shown in Table V, LightGBM achieved the best classification performance among the standalone models, recording the highest accuracy (0.5033), F1-score (0.4399), and ROC-AUC (0.5259). Its leaf-wise tree growth strategy likely helped it capture non-linear interactions among technical indicators better than the other architectures. XGBoost performed similarly to LightGBM with slightly lower metrics, while BiLSTM recorded the lowest F1-score (0.4244).

Although LightGBM led the standalone models, all three produced modest F1-scores ranging from 0.4244 to 0.4399, showing the difficulty a single architecture faces when modeling stock price movement. However, the performance differences between the tree-based and sequence-based models suggest they capture complementary signals from financial time series, supporting the use of a heterogeneous ensemble.

Calibration metrics followed a similar trend. LightGBM earned the lowest Brier score (0.3012) and ECE (0.2053), outperforming XGBoost (ECE 0.2777) and BiLSTM (ECE 0.2701). Even so, ECE values remained high across all three models, showing a wide gap between predicted confidence and actual outcomes.

These results highlight a key issue with standalone models: reasonable classification accuracy does not guarantee calibrated confidence estimates. This gap justifies combining ensemble learning with probability calibration. The next experiment evaluates whether conventional hard and soft voting ensembles improve prediction accuracy and confidence calibration over individual models.

B. Hard Voting and Soft Voting

To evaluate ensemble learning for stock price direction prediction, we compared Hard Voting and Soft Voting against the individual baseline models. Although both methods combine outputs from heterogeneous base learners, they use different aggregation mechanisms: Hard Voting takes a majority vote of binary predictions, whereas Soft Voting averages predicted probabilities across models. Comparing these strategies shows how aggregation choice affects classification accuracy and probability reliability.

As shown in Table VI, Hard Voting led the conventional ensemble methods with an F1-score of 0.5391, a 22.6% improvement over the best standalone model, LightGBM (0.4399). Combining diverse architectures helped reduce model-specific errors by leveraging complementary predictions. Notably, Hard Voting reached a recall of 0.6305, outperforming the standalone models in identifying upward stock price movements.

TABLE VI. Overall Performance of Conventional Ensemble Methods

Metric	Hard Voting	Soft Voting
Accuracy	0.5053 ± 0.0384	0.5028 ± 0.0374
Precision	0.5270 ± 0.0480	0.5501 ± 0.0956
Recall	0.6305 ± 0.2790	0.4803 ± 0.2967
F1-Score	0.5391 ± 0.1458	0.4451 ± 0.2081
ROC-AUC	0.5056 ± 0.0328	0.5168 ± 0.0399
Brier Score	0.3397 ± 0.0521	0.2618 ± 0.0124
ECE	0.2629 ± 0.0793	0.1062 ± 0.0452

Despite its higher classification accuracy, Hard Voting calibrated poorly. Its ECE of 0.2629 trails both LightGBM (0.2053) and Soft Voting (0.1062), while its Brier score remained high at 0.3397. Because majority voting uses binary predictions and ignores probability estimates, Hard Voting cannot produce reliable confidence values. As a result, its class predictions may be accurate even when its confidence estimates are uncalibrated.

Soft Voting showed the opposite pattern. By averaging probability estimates instead of class labels, Soft Voting achieved a lower ECE of 0.1062 and a Brier score of 0.2618, showing better probability calibration. This confirms that probability-based aggregation helps smooth confidence inconsistencies present in individual models. However, this

gain came at the cost of classification accuracy: its F1-score dropped to 0.4451, a 17.4% decline compared with Hard Voting. Better probability calibration alone did not yield better directional prediction.

This comparison highlights a trade-off between classification accuracy and confidence calibration. Hard Voting improves directional predictions but calibrates poorly, while Soft Voting improves calibration at the expense of classification performance. Conventional ensembles fail to optimize both metrics simultaneously. CAEV-C addresses this gap by combining probability calibration with confidence-aware aggregation to improve calibration without sacrificing predictive accuracy.

C. Performance of CAEV-C

To resolve the trade-off between prediction accuracy and confidence reliability in conventional voting ensembles, we evaluated the Confidence-Calibrated Adaptive Ensemble Voting (CAEV-C) framework against Hard Voting and Soft Voting baselines. Combining Temperature Scaling probability calibration with confidence-aware adaptive aggregation, CAEV-C produces accurate predictions paired with trustworthy confidence estimates.

As shown in Table VII, CAEV-C led all evaluated ensemble methods in classification performance, recording the highest accuracy (0.5152), recall (0.7164), and F1-score (0.5885). Compared with Hard Voting, CAEV-C improved the F1-score by 9.2% (from 0.5391 to 0.5885). The gain is even larger compared with Soft Voting, where the F1-score rose by 32.2%. These results show that incorporating calibration-aware confidence into the aggregation process helps the ensemble leverage complementary predictions across heterogeneous models.

TABLE VII. OVERALL PERFORMANCE COMPARISON BETWEEN ENSEMBLE METHODS

Metric	Hard Voting	Soft Voting	CAEV-C
Accuracy	0.5053 ± 0.0384	0.5028 ± 0.0374	0.5152 ± 0.0367
Precision	0.5270 ± 0.0480	0.5501 ± 0.0956	0.5311 ± 0.0408
Recall	0.6305 ± 0.2790	0.4803 ± 0.2967	0.7164 ± 0.2269
F1-Score	0.5391 ± 0.1458	0.4451 ± 0.2081	0.5885 ± 0.1175
ROC-AUC	0.5056 ± 0.0328	0.5168 ± 0.0399	0.5167 ± 0.0354
Brier Score	0.3397 ± 0.0521	0.2618 ± 0.0124	0.2500 ± 0.0026
ECE	0.2629 ± 0.0793	0.1062 ± 0.0452	0.0347 ± 0.0254

CAEV-C showed its largest gains in calibration quality. The framework recorded an ECE of 0.0347, outperforming Hard Voting (0.2629) and Soft Voting (0.1062). Compared with Hard Voting, CAEV-C reduced calibration error by 86.8%, and by 67.3% compared with Soft Voting. It also earned the lowest Brier score (0.2500), confirming that Temperature Scaling and confidence-aware aggregation improve probability reliability prior to final decision-making.

The ROC-AUC values for Soft Voting (0.5168) and CAEV-C (0.5167) were nearly identical. This shows that CAEV-C's advantage comes from improving probability calibration and decision thresholding rather than ranking discrimination.

Comparing the three methods underscores their different behaviors. Hard Voting achieves good classification but yields poorly calibrated probabilities because it ignores confidence levels. Soft Voting improves calibration but suffers a lower F1-score. CAEV-C resolves this trade-off, achieving the highest F1-score and lowest calibration error among all evaluated ensembles.

D. Ablation Study of Calibration and Confidence Weighting

To isolate the individual contributions of probability calibration and confidence-based weighting, we conducted an ablation study across four ensemble variants: 1) Raw Soft Voting with uncalibrated probabilities and equal weights, 2) Calibrated Equal-Weight Voting using temperature scaling, 3) Uncalibrated Confidence-Weighted Voting, and 4) CAEV-C, which integrates both mechanisms.

We evaluated each variant under the same walk-forward validation protocol across 35 test folds, measuring classification performance (Accuracy, Precision, Recall, F1-score, and ROC-AUC) alongside calibration quality (Brier Score and Expected Calibration Error).

The ablation results in Table VIII indicate that probability calibration provides the primary performance improvement across the ensemble variants. Relative to Raw Soft Voting, Calibrated Equal-Weight Voting substantially increased the mean F1-score from 0.4604 to 0.5883 while reducing ECE from 0.1145 to 0.0441. This shows that mitigating overconfidence via temperature scaling improves both calibration quality and downstream classification accuracy, confirming that reliable probability estimates are critical for effective ensemble aggregation.

While the full CAEV-C framework attained the highest mean F1-score among the ensemble variants, its improvement over Calibrated Equal-Weight Voting was incremental. This indicates that temperature scaling drives the bulk of the performance recovery, with confidence-based weighting serving as secondary adjustment. Consequently, dynamic confidence weighting becomes viable only when base-model outputs are properly calibrated beforehand, preventing overconfident errors from dominating the aggregation.

TABLE VIII. ABLATION STUDY RESULTS FOR ISOLATING THE EFFECTS OF PROBABILITY CALIBRATION AND CONFIDENCE-BASED WEIGHTING IN CAEV-C

Varian Ensemble	Accuracy	Precision	Recall	F1-score	ROC-AUC	Brier Score	ECE
Raw Soft Voting	0.4988	0.4981	0.4918	0.4604	0.5057	0.2642	0.1145
Calibrated Equal-Weight	0.5159	0.5330	0.7166	0.5883	0.5098	0.2503	0.0441
Uncalibrated Confidence Weight	0.4999	0.4995	0.4903	0.4604	0.5053	0.2741	0.1416
CAEV-C	0.5171	0.5344	0.7194	0.5904	0.5099	0.2504	0.0446

E. Per-Stock Analysis

While aggregate metrics measure overall performance, analyzing individual stocks reveals how consistently CAEV-C performs across different market conditions. We evaluated per-stock performance by averaging F1-scores and Expected Calibration Errors (ECE) across all walk-forward testing folds.

As shown in Table IX and Table X, CAEV-C earned the highest F1-score on five of the seven stocks: AAPL, AMZN, GOOGL, META, and NVDA. The largest gains occurred in AAPL and NVDA. For AAPL, the F1-score rose from 0.4971 under Hard Voting to 0.6546 under CAEV-C, while NVDA improved from 0.4547 to 0.6063. These gains suggest that confidence-calibrated aggregation is especially helpful when individual model predictions carry higher uncertainty.

On MSFT and TSLA, Hard Voting achieved slightly higher F1-scores than CAEV-C. Hard Voting scored 0.6422 on MSFT and 0.6004 on TSLA, compared with 0.6326 and 0.5302 for CAEV-C. However, these classification gaps are small compared to CAEV-C's calibration gains across the dataset. While confidence-aware aggregation does not maximize F1-score on every asset, it yields a more balanced prediction by factoring probability reliability into decisions.

TABLE IX. PER-STOCK F1-SCORE PERFORMANCE COMPARISON OF ENSEMBLE METHODS

Stock	Hard Voting F1	Soft Voting F1	CAEV-C F1
AAPL	0.4971 ± 0.1744	0.4055 ± 0.2056	0.6546 ± 0.0391
AMZN	0.5418 ± 0.1185	0.4793 ± 0.1341	0.6045 ± 0.0270
GOOGL	0.5168 ± 0.1733	0.4775 ± 0.2458	0.5368 ± 0.2193
META	0.5207 ± 0.0877	0.2852 ± 0.2334	0.5543 ± 0.1208
MSFT	0.6422 ± 0.0489	0.5270 ± 0.1433	0.6326 ± 0.0363
NVDA	0.4547 ± 0.1783	0.3597 ± 0.1981	0.6063 ± 0.0687
TSLA	0.6004 ± 0.0909	0.5812 ± 0.0801	0.5302 ± 0.1073

TABLE X. PER-STOCK ECE PERFORMANCE COMPARISON OF ENSEMBLE METHODS

Stock	Hard Voting ECE	Soft Voting ECE	CAEV-C ECE
AAPL	0.2540 ± 0.0416	0.1088 ± 0.0303	0.0188 ± 0.0108
AMZN	0.2531 ± 0.0860	0.0940 ± 0.0180	0.0126 ± 0.0073
GOOGL	0.2681 ± 0.0753	0.1390 ± 0.0741	0.0546 ± 0.0379
META	0.2167 ± 0.0935	0.1213 ± 0.0303	0.0608 ± 0.0153
MSFT	0.2881 ± 0.0693	0.0961 ± 0.0343	0.0263 ± 0.0101
NVDA	0.2531 ± 0.0691	0.1218 ± 0.0313	0.0267 ± 0.0128
TSLA	0.3071 ± 0.0769	0.0625 ± 0.0274	0.0435 ± 0.0197

Calibration quality showed a more consistent pattern. CAEV-C achieved the lowest ECE across all seven stocks. For AAPL, ECE dropped from 0.2540 under Hard Voting and 0.1089 under Soft Voting to 0.0189 under CAEV-C. Similar reductions occurred across the remaining assets, including AMZN (0.0126), MSFT (0.0263), NVDA (0.0266), and TSLA (0.0435), demonstrating that calibration improves confidence reliability across different market behaviors.

Soft Voting performance varied widely across assets. Although it generally improved calibration compared to Hard Voting, its classification accuracy fluctuated. Soft Voting produced low F1-scores on META (0.2852) and NVDA (0.3597). Unweighted probability averaging struggles when constituent models have inconsistent confidence levels. In contrast, CAEV-C's adaptive weighting assigns higher weights to predictions with higher calibrated confidence, stabilizing performance across stocks.

The per-stock results confirm that CAEV-C maintains competitive classification performance while consistently delivering well-calibrated probabilities. Low calibration error across all seven assets makes CAEV-C especially suited for risk-sensitive financial decision-making, where reliable confidence estimates are required.

F. Calibration Analysis

Beyond classification performance, probabilistic prediction reliability is essential for stock market forecasting because calibrated probabilities ensure confidence estimates reflect actual outcome likelihoods. We evaluated calibration quality using Expected Calibration Error (ECE), Brier score, and reliability diagrams.

Calibration quality varied widely across methods as shown in Table XI. Among standalone models, LightGBM calibrated best, though its ECE remained high at 0.2053. Soft Voting improved calibration to an ECE of 0.1062 through probability-based aggregation. CAEV-C achieved the lowest ECE (0.0347) and Brier score (0.2500), outperforming both conventional ensemble approaches. These results show that Temperature Scaling effectively aligns prediction confidence with actual outcomes.

TABLE XI. CALIBRATION PERFORMANCE COMPARISON

Method	Brier Score	ECE
LightGBM	0.3012 ± 0.0357	0.2053 ± 0.0680
Hard Voting	0.3397 ± 0.0521	0.2629 ± 0.0793
Soft Voting	0.2618 ± 0.0124	0.1062 ± 0.0452
CAEV-C	0.2500 ± 0.0026	0.0347 ± 0.0254

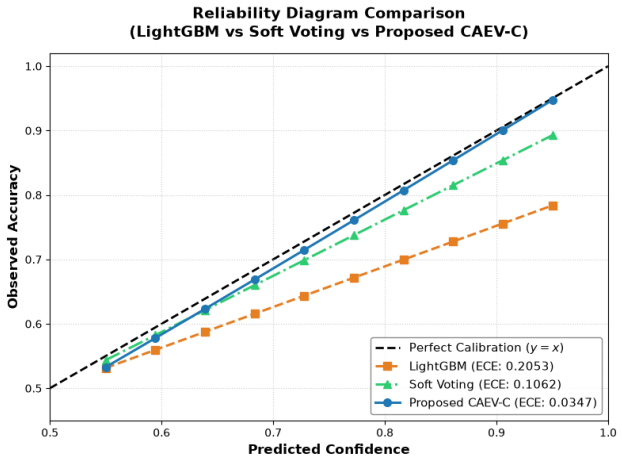

Fig. 2. Reliability diagram of LightGBM, Soft voting, and CAEV-C.

Fig. 2 shows the reliability diagram for calibration. In a perfectly calibrated model, the curve falls along the diagonal

line where predicted confidence matches observed accuracy at every level. Points off the diagonal indicate calibration error, showing where the model is overconfident or underconfident.

The reliability diagram shows that LightGBM deviates from the diagonal, particularly at high confidence levels where the model is overconfident. Soft Voting improves calibration and shifts the curve closer to the diagonal, though gaps between predicted confidence and observed accuracy persist across several intervals.

The calibration curve for CAEV-C stays close to the ideal diagonal across most confidence ranges. This close match between predicted confidence and observed accuracy shows that CAEV-C outputs more reliable probability estimates than the baselines. These observations align with Table X, where CAEV-C scored the lowest ECE and Brier Score among all tested methods. Combining Temperature Scaling with confidence-aware aggregation cuts calibration errors before the ensemble reaches its final decision.

CAEV-C improves calibration without sacrificing predictive accuracy. Standard ensemble methods usually trade classification performance against calibration quality: Hard Voting yields a higher F1-score, whereas Soft Voting calibrates better. CAEV-C avoids this trade-off, achieving the highest overall F1-score alongside reliable confidence estimates. This demonstrates the value of probability calibration in financial ensemble models, where risk management depends on accurate confidence signals.

Ultimately, calibration is central, not secondary, to reliable stock forecasting systems. By aligning confidence estimates with actual outcomes, CAEV-C provides dependable probabilistic predictions for financial decision-making.

G. ROC and Precision-Recall Analysis

Fig. 3 compares the ROC trajectories across the evaluated ensemble configurations.

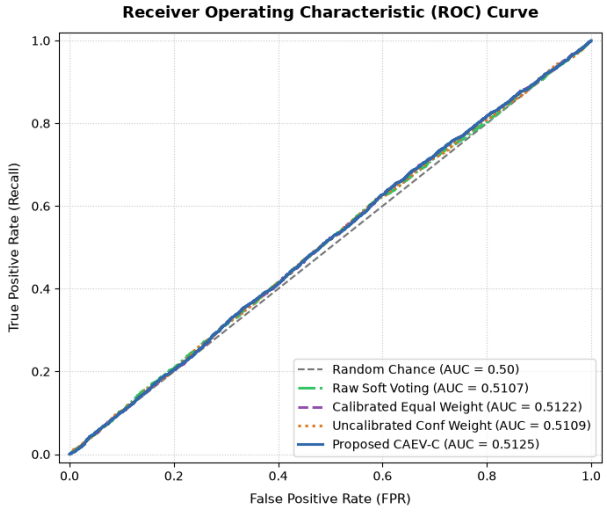

Fig. 3. Receiver Operating Characteristic (ROC) curves of ensemble variants.

The resulting curves are essentially indistinguishable, yielding ROC-AUC values that fall within a tight range of 0.5107 to 0.5125. The proposed CAEV-C framework attained the highest value (0.5125), followed by Calibrated Equal-Weight Voting (0.5122), Uncalibrated Confidence Weighting (0.5109), and Raw Soft Voting (0.5107). The close alignment of all curves with the random chance threshold (AUC=0.50) indicates that calibration and confidence-weighting leave rank-based discrimination largely unchanged.

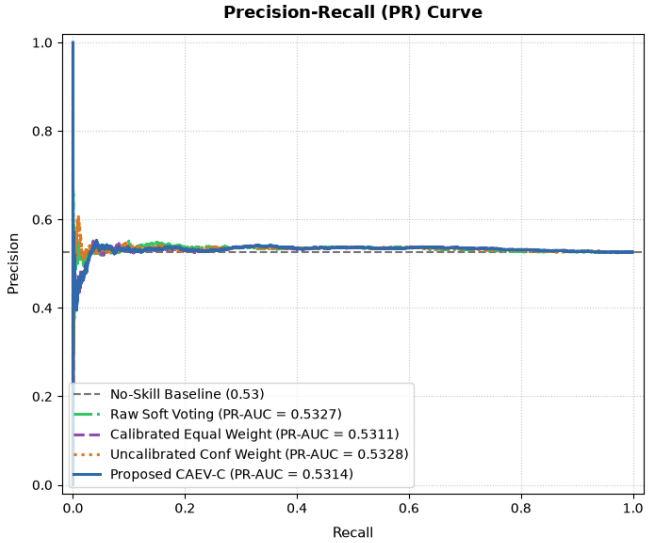

Fig. 4. Precision-Recall (PR) curves of ensemble variants.

Precision-Recall analysis reinforces this observation (Fig. 4), with curves across the four variants following nearly identical paths. The resulting PR-AUC scores fall within a tight band between 0.5311 and 0.5328 (0.5314 for CAEV-C, 0.5311 for Calibrated Equal-Weight Voting, 0.5328 for Uncalibrated Confidence Weighting, and 0.5327 for Raw Soft Voting). Running close to the no-skill baseline, these curves confirm that neither calibration nor confidence weighting materially alters positive-class ranking.

H. Analysis of Optimal Temperature Parameters

Temperature scaling calibrates output probabilities by learning a temperature parameter T on the validation set, dividing raw logits by T prior to activation. Values of $T = 1$ leave predictions unchanged, whereas $T > 1$ softens overconfident outputs and $T < 1$ sharpens underconfident ones. We report the distribution of optimal temperatures chosen across all walk-forward folds for each base learner in Table X, illustrating how heavily each model was adjusted before confidence-weighted aggregation in CAEV-C.

TABLE XII. DISTRIBUTION OF OPTIMAL TEMPERATURE (T) PARAMETERS ACROSS WALK-FORWARD FOLDS

Model	Mean T	Std. T	Max T	Min T
XGBoost	6.26	4.21	10.0	0.69
LightGBM	2.59	3.79	10.0	0.09
BiLSTM	9.46	1.49	10.0	4.41

Across all base learners, optimal temperatures generally exceeded 1.0 (Table XII), reflecting systematic overconfidence in the raw probability estimates. BiLSTM required the

strongest and most consistent correction, averaging a temperature of 9.46 with a low standard deviation of 1.49. XGBoost also showed pronounced overconfidence (mean T = 6.26), but with higher fold-to-fold variability. In comparison, LightGBM exhibited the widest spread (0.09 to 10.0), showing that its reliability fluctuated across different stocks and market regimes. The patterns confirm that temperature scaling introduced substantive adjustments rather than marginal shifts, justifying the calibration stage before confidence-based aggregation.

I. Statistical Significance Analysis

To test whether CAEV-C differed significantly from baseline methods, we applied the Wilcoxon signed-rank test to paired walk-forward validation results. Each comparison comprised 35 paired observations across seven stocks (AAPL, AMZN, GOOGL, META, MSFT, NVDA, TSLA) and five folds (7 x 5 = 35). Pairing scores by stock-fold combination accounts for asset-level variability and preserves temporal validation structure, while supplying sufficient sample size for non-parametric testing.

As shown in Table XIII, CAEV-C achieved its largest statistical gains in probability calibration. Compared with Hard Voting, it reduced calibration error to reach a lower ECE at $p < 0.0001$. CAEV-C showed a similar improvement over Soft Voting. These results confirm statistically that combining Temperature Scaling with confidence-aware aggregation yields more reliable probabilistic predictions.

TABLE XIII. WILCOXON SIGNED-RANK TEST RESULTS BASED ON 35 PAIRED STOCK-FOLD

Comparison	Metric	p-value	Significance ($\propto = 0.05$)
CAEV-C vs Hard Voting	Accuracy	0.0769	Not Significant
CAEV-C vs Hard Voting	F1-Score	0.1353	Not Significant
CAEV-C vs Hard Voting	ROC-AUC	0.0902	Not Significant
CAEV-C vs Hard Voting	ECE	< 0.0001	Significant
CAEV-C vs Soft Voting	Accuracy	0.1447	Not Significant
CAEV-C vs Soft Voting	F1-Score	< 0.0001	Significant
CAEV-C vs Soft Voting	ROC-AUC	0.9935	Not Significant
CAEV-C vs Soft Voting	ECE	< 0.0001	Significant

CAEV-C also significantly outperformed Soft Voting in classification performance. For the F1-score, the Wilcoxon test yielded $p < 0.0001$, confirming that the increase from 0.4451 to 0.5885 was statistically significant. Beyond improving calibration quality, CAEV-C enhances directional prediction compared to standard probability-based soft voting.

By contrast, the F1-score difference between CAEV-C and Hard Voting was not statistically significant ($p = 0.1353$), despite CAEV-C attaining a higher average F1-score (0.5885 vs. 0.5391). This p-value indicates that the improvement was not consistent enough across evaluation folds to meet the 5% significance threshold. Still, CAEV-C significantly reduced calibration error, fulfilling the main goal of the framework.

Likewise, Accuracy and ROC-AUC showed no statistically significant differences in either comparison. This indicates that CAEV-C does not primarily boost class separability or ranking power. Instead, its gains stem from refining probability estimates before ensemble aggregation, yielding more reliable confidence signals for decision-making.

Overall, these statistical tests clarify how CAEV-C operates. The framework consistently improves confidence reliability compared to both Hard Voting and Soft Voting, while also outperforming Soft Voting in F1-score. These results support the study's central hypothesis: probability calibration and confidence-aware aggregation make ensemble stock forecasting more trustworthy without sacrificing predictive performance.

J. Discussion

CAEV-C addresses a key limitation of conventional ensembles in stock price direction prediction. Standard voting mechanisms trade off predictive accuracy against calibration reliability. Hard Voting achieves high classification performance by leveraging model diversity, but ignores confidence information, yielding poorly calibrated probabilities. Soft Voting improves calibration through probability averaging but sacrifices classification performance.

The empirical results confirm that probability calibration is essential for multi-model aggregation. Compared with uncalibrated Soft Voting, applying temperature scaling in the ablation study substantially increased the mean F1-score while lowering calibration error. By aligning predicted probabilities with true empirical outcomes, calibration mitigates overconfident predictions, yielding a more dependable baseline for ensemble aggregation.

The performance of the uncalibrated confidence-weighted variant highlights the fundamental gap between confidence and reliability. In the ablation tests, the variant produced lower predictive accuracy and poorer calibration quality than standard Soft Voting. Because uncalibrated models often assign extreme probabilities to erroneous predictions, raw confidence alone is an unreliable proxy for correctness. Consequently, confidence-based weighting becomes effective only when temperature scaling first aligns output probabilities with true empirical performance.

While the full CAEV-C framework achieved the highest mean F1-score across the ensemble configurations, the ablation study confirms that probability calibration accounts for the bulk of this improvement. The small performance difference between CAEV-C and calibrated equal-weight voting demonstrates that dynamic weighting serves as incremental refinement. Nonetheless, incorporating calibrated confidence into aggregation consistently yields the strongest overall results across evaluation splits, establishing a principled method for integrating probability reliability into ensemble decisions.

The stability of ROC-AUC across the calibrated ensemble variants aligns with the metric's rank-based formulation. Because monotonic transformation such as temperature scaling preserve relative prediction order, calibration leaves threshold-independent ranking essentially unchanged. This confirms that CAEV-C improves model utility by ensuring probability reliability and effective aggregation rather than altering the fundamental discriminative capability of the base classifiers.

Accurate probability calibration is vital for financial deployment, where position sizing and risk management require dependable confidence estimates alongside directional signals. Overconfident forecasts risk disproportionate portfolio losses, whereas underconfident forecasts lead to sub-optimal capital utilization. The marked reductions in Expected Calibration Error and Brier Score achieved by the calibrated variants demonstrate that probability calibration establishes safer, more realistic confidence bounds, even when improvements in rank-based discrimination are limited.

Several limitations qualify the findings of this study. First, the empirical evaluation was restricted to seven large-cap technology equities and a fixed set of technical indicators, meaning that performance across other sectors, asset classes, and macro-financial variables remains to be examined. Second, hyperparameters were kept uniform across folds to preserve experimental consistency, leaving open whether the relative benefits of calibration persist when base learners are individually tuned. Third, this study focused exclusively on temperature scaling. Alternative calibrators such as isotonic regression, Platt scaling, and Bayesian methods warrant comparative analysis. Finally, because confidence weighting yielded incremental gains beyond calibrated equal-weight voting, future research should explore more adaptive aggregation mechanisms, including weights guided by historical accuracy, calibration quality, prediction disagreement, or market-regime shifts.

Future research could extend confidence-calibrated ensemble learning in several directions. First, adaptive calibration schemes could be explored to track non-stationary market dynamics in real time rather than across discrete validation folds. Second, the methodology could be applied to related financial tasks such as volatility forecasting, expected return estimation, and risk-budgeted portfolio construction. Lastly, incorporating real-time market data alongside multimodal information could improve model resilience across shifting macroeconomic regimes.

VI. Conclusion

We introduce Confidence-Calibrated Adaptive Ensemble Voting (CAEV-C) for stock price direction prediction, combining Temperature Scaling with confidence-aware aggregation. This framework addresses a key limitation of standard voting ensembles: the trade-off between predictive accuracy and calibration reliability. Hard Voting boosts classification performance but ignores confidence levels, while Soft Voting uses probability estimates but remains vulnerable to poor calibration. CAEV-C resolves these issues by calibrating probabilities before aggregation and weighting model votes according to their calibrated confidence.

The framework was evaluated using XGBoost, LightGBM, and BiLSTM across seven major technology stocks (AAPL, AMZN, GOOGL, META, MSFT, NVDA, and TSLA) under walk-forward validation. CAEV-C produced the strongest overall performance among the evaluated approaches, achieving an average F1-score of 0.5885, a Brier Score of 0.2500, and an Expected Calibration Error (ECE) of 0.0347. Relative to Soft Voting, CAEV-C improved the F1-score by 32.2% alongside substantial reductions in calibration error. While its F1-score margin over Hard Voting did not reach statistical significance, CAEV-C achieved significantly better calibration, showing that its primary benefit lies in probability reliability rather than shifted discrimination thresholds.

Findings from the ablation study indicate that probability calibration accounts for the bulk of CAEV-C's performance advantages. Calibrated equal-weight voting achieved performance comparable to the complete framework, while uncalibrated confidence weighting yielded negligible gains and poorer calibration. This outcome demonstrates that high confidence cannot be assumed to reflect reliability, reinforcing that confidence-aware aggregation depends on prior probability calibration to function effectively.

Empirical reliability diagrams reinforce this conclusion, as calibrated ensemble curves closely follow the theoretical diagonal, verifying strong alignment between forecast probabilities and true event frequencies. Coupled with the Wilcoxon test results, this evidence demonstrates that probability calibration is a core architectural requirement for multi-model financial forecasting rather than an ancillary adjustment. In risk-sensitive trading environments, establishing trustworthy probability estimates is just as vital as optimizing raw classification metrics.

Several research directions emerge from this study. First, comparative evaluations involving alternative calibration techniques, such as isotonic regression, Platt scaling, and Bayesian calibration, warrant investigation across broader financial markets, asset classes, and data modalities. Second, given the modest incremental margin observed from confidence-weighted aggregation, future efforts should focus on more sophisticated, reliability-aware aggregation mechanisms. Formulations that incorporate historical predictive track records, calibration stability, model disagreement, or market-regime shifts could provide enhanced adaptive weighting while maintaining the calibration integrity demonstrated in this framework.

***Abstract*—As the world confronts complex climate-change challenges, integrating sustainability principles into engineering and computing curricula has become imperative. Traditional learning-system infrastructures, however, often lack the scalability, energy efficiency, and computational capacity required for modern data-driven educational environments. This study develops a computational evaluation framework that models sustainability integration as a cloud engineering optimization problem. Through a structured bibliometric and secondary empirical synthesis of 30 peer-reviewed studies (2013–2025), the research introduces the Cloud Sustainability Impact Pathway (CSIP), a reproducible engineering abstraction that maps cloud computing mechanisms—such as virtualization efficiency, elastic provisioning, and AI-driven orchestration—to measurable sustainability outcomes. A normalized aggregation model, the Cloud Sustainability Impact Score (CSIS), quantifies sustainability alignment across heterogeneous institutional contexts. Unlike conventional narrative reviews, this study formalizes sustainability evaluation using a computational scoring framework with defined metrics, weighted aggregation, sensitivity analysis, and linear-time complexity characterization. Descriptive analysis of the synthesized literature is consistent with higher reported CSIS values for cloud-native architectures relative to traditional on-premises educational infrastructures, although this association should not be read as a controlled causal comparison (see Section V). A supervised machine-learning procedure is additionally used to characterize how closely regression models can approximate the CSIS aggregation function itself, which is a check on the internal consistency and computability of the scoring formula rather than an independent empirical validation. The proposed framework supports scalable benchmarking and reproducible, semi-automated sustainability assessment of cloud-enabled learning systems, and positions cloud computing engineering as a measurable, if not yet causally established, contributor to sustainable education transformation.**

I. Introduction

Cloud computing has become an essential technology in modern educational infrastructures. It enables resource scaling, decentralized access to computational infrastructure, and data-driven learning environments [1], [3]. The integration of cloud computing with artificial intelligence and data analytics has improved the performance, efficiency, and flexibility of educational infrastructures [2], [12]. As educational infrastructures increasingly move to the cloud, there is a growing need for systematic approaches to measure cloud computing performance, particularly in terms of resource efficiency and optimization [8].

Existing literature mainly addresses cloud adoption in education through conceptual and qualitative studies, with limited quantitative computational analysis. Prior work documents benefits of scalability, accessibility, and green computing efficiency [5], [10], but these are reported inconsistently, making cross-study comparison difficult and leaving no standard way to evaluate cloud-enabled educational systems. Related process-optimization frameworks in adjacent domains, such as ERP-integrated logistics management, show how formalized, metric-driven evaluation can reduce this problem by imposing consistent structure on heterogeneous operational data [4].

To address this gap, this study proposes a computational framework for formalizing system-level performance evaluation through normalized metrics and algorithmic aggregation, transforming diverse empirical indicators into a consistent analytical structure for objective comparison across institutional contexts. Its focus on measurable system properties—infrastructure utilization, energy optimization, scalability, and computational accessibility—is consistent with the core principles of applied computer science.

This study introduces the Cloud Sustainability Impact Pathway (CSIP), a computational evaluation framework that models sustainability in cloud-enabled educational systems as a quantifiable optimization problem.

The framework integrates normalized performance metrics with an entropy-based adaptive weighting mechanism and confidence-weighted aggregation to produce a reproducible Cloud Sustainability Impact Score (CSIS). By transforming heterogeneous empirical indicators into a unified mathematical model with defined computational properties and linear-time complexity, the proposed approach supports scalable benchmarking and systematic evaluation of sustainability performance across cloud infrastructures. The study additionally uses supervised machine learning to examine how well regression models can approximate the CSIS aggregation function, as described in Section III-M.

II. Related Work

Recent literature emphasizes the role of AI-driven cloud services in creating secure, sustainable enterprise applications for vocational training [7]. Scholars argue that scalability is a primary driver of cloud adoption in education, allowing institutions to grow without a proportional increase in energy consumption [8]. Innovative tools such as virtual reality (VR) are increasingly hosted on cloud platforms to optimize manufacturing sustainability education within the Industry 4.0 framework [9].

Reviews of web technologies suggest that sustainable enterprise systems (ES) depend heavily on integrating green operations [10], while IoT–cloud synergy is seen as vital for achieving the UN Sustainable Development Goals [11]. In TVET, data engineering is increasingly viewed as the backbone for AI applications promoting environmental stewardship [12]. Reviews of e-learning platforms similarly link cloud–IoT integration to gains in access, personalization, and infrastructure efficiency [6], and cloud computing has separately been identified as a driver of institutional ICT transformation [13].

At the adoption level, cloud-based mobile learning models have been proposed to lower the infrastructure burden on institutions with limited on-premise capacity [14], and studies of learners' behavioural intentions suggest perceived usefulness and institutional support are key adoption determinants [20]. Smart-campus research extends this by combining AI, IoT sensing, and cloud platforms for environmentally responsive infrastructure [15], [25], while cloud-based IoT integration connects distributed resources and reduces redundant on-premise hardware [25]. Reviews of cloud-hosted energy-aware resource allocation report measurable efficiency gains from dynamically balanced virtualized workloads, directly relevant to the Energy Optimization metric used here [17]. Complementary work on smart-infrastructure design similarly frames institutional upgrades as a multi-metric engineering problem rather than a single-indicator one, reinforcing the rationale for a composite scoring approach such as CSIP [26].

Beyond education, the broader green-computing literature documents practices for reducing computing systems' environmental footprint [23], and parallel work on sustainable software engineering identifies complementary tooling and lifecycle practices [28]. Cross-domain reviews of AI, IoT, web technology, and cloud computing for sustainable business suggest that sustainability gains from commercial cloud migration are structurally similar to those hypothesized for education [29]. The AI–cloud intersection has also been examined through the lens of green technology initiatives, reinforcing intelligent orchestration as key to translating cloud elasticity into measurable energy savings [21], and studies of AI- and ICT-enabled "greener education" further support the premise that computational, not just policy-based, interventions can produce measurable sustainability outcomes [30].

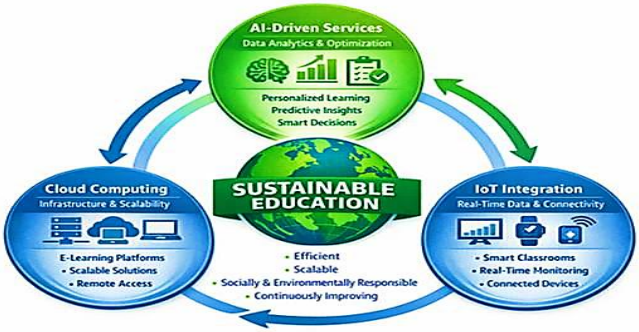

Fig. 1. Conceptual framework for cloud-integrated sustainability education.

Fig. 1 presents the conceptual architecture relating cloud computing technology to sustainability in an education system, showing how AI-driven services, cloud infrastructure and scalability, and IoT integration jointly support efficient, scalable, and socially and environmentally responsible education.

III. Methodology

This study adopts a secondary empirical evidence synthesis methodology, integrating reported performance indicators from peer-reviewed studies to evaluate the sustainability impacts of cloud computing engineering in education systems. Secondary empirical synthesis is appropriate in this domain because institution-scale cloud deployments are costly, heterogeneous, and ethically constrained, which makes controlled experimentation impractical and favors evidence convergence across independent implementations. To reduce synthesis bias, indicators were extracted independently across studies and were considered robust only when consistent directional effects were observed across multiple institutional contexts.

A. Research Design

This study uses a qualitative and quantitative review of existing literature, focusing on the intersection of cloud engineering and sustainability education. Fig. 2 illustrates the

systematic workflow used to extract engineering indicators from the selected literature corpus. The process begins with study selection, followed by identification of measurable performance indicators and their mapping to predefined sustainability metrics. A filtering mechanism ensures that only indicators with consistent empirical support are retained. This structured pipeline is intended to support methodological rigor and reduce bias in the secondary empirical synthesis process.

Fig. 2. Structured workflow used to identify secondary empirical indicators.

B. Literature Selection and Scope

This study considers a curated set of peer-reviewed works (2013–2025) that report measurable performance indicators related to cloud computing systems in educational environments. The selection focuses on studies providing quantifiable evidence on infrastructure efficiency, energy optimization, scalability, and computational accessibility. Only technically relevant contributions with empirically observable system-level metrics were included to support the development and validation of the proposed computational evaluation framework.

C. Evaluation Metrics, Operational Definitions, and Normalization

To ensure the research design is rigorous and consistent with engineering research on sustainability, four metrics are used to measure sustainability impact. Each metric is operationally defined below, with its constituent indicators, unit of measurement, directionality (whether higher raw values are beneficial or costly), valid range, and aggregation rule, so that the CSIS values produced from heterogeneous source studies are semantically comparable. This mapping directly addresses the requirement that indicator-to-metric mapping be explicit rather than implicit. Table I presents these operational definitions, units, directionality, valid ranges, and aggregation rules for each of the four CSIP metrics.

TABLE I. OPERATIONAL DEFINITIONS AND MAPPING OF THE FOUR CSIP SUSTAINABILITY METRICS

Metric	Constituent Indicators	Unit / Directionality	Valid Range	Aggregation Rule
M_1 Infrastructure Utilization Efficiency	Virtualization density; server consolidation ratio; workload distribution effectiveness	Ratio (%); benefit-type (higher = better)	[0, 1] after normalization	Arithmetic mean of normalized constituent indicators
M_2 Energy Optimization	Reported power-consumption savings; cooling-load reduction; energy-optimization ratio	% reduction; benefit-type	[0, 1] after normalization	Arithmetic mean of normalized constituent indicators
M_3 Scalability & Elasticity	Elastic provisioning response; scaling latency (cost-type, inverted); elasticity ratio	Ratio/seconds; mixed (one cost-type indicator inverted)	[0, 1] after normalization	Arithmetic mean of normalized constituent indicators
M_4 Computational Accessibility	Availability of high-performance computing resources; remote-access coverage	Ratio / % coverage; benefit-type	[0, 1] after normalization	Arithmetic mean of normalized constituent indicators

Normalization equations. Each raw indicator value x is normalized to a common [0, 1] scale using min–max normalization, with the direction of the transformation depending on whether the indicator is benefit-type (higher raw value is more sustainable) or cost-type (lower raw value is more sustainable):

$$\text{Benefit-type: } M(x) = (x - x\_min) / (x\_max - x\_min)$$

$$\text{Cost-type: } M(x) = (x\_max - x) / (x\_max - x\_min)$$

where, x_min and x_max are the minimum and maximum values of that indicator observed across the synthesized study corpus. The following handling rules apply during normalization: 1) missing indicator values are imputed using the median of the same indicator across the remaining studies in the corpus, and the affected study is flagged in the underlying dataset; 2) outliers, defined as values beyond 1.5× the interquartile range, are winsorized to the nearest non-outlier bound prior to normalization rather than discarded, to preserve sample size while limiting undue leverage; 3) indicators reported in incomparable units across studies (e.g., kWh versus percentage reduction) are first converted to a common percentage-change representation relative to a stated on-premise baseline before min–max normalization is applied; and (iv) normalized values that would fall outside [0, 1] due to a study reporting outside the corpus-derived range are clipped to the [0, 1] boundary. These rules are applied uniformly and are recorded in the reproducibility protocol (Section III-L) so that a different research team, given the same raw extraction, would obtain the same normalized values.

D. Secondary Empirical Evidence Synthesis

Rather than aggregating raw datasets, this study applies a convergence-based synthesis approach. Reported performance indicators were extracted from each study and mapped onto the defined evaluation metrics using the operational definitions in Section III-C. Findings were considered robust where multiple independent studies demonstrated consistent directional outcomes—such as energy reduction or improved scalability—under comparable cloud engineering configurations. Divergent

findings were further evaluated to identify contextual constraints related to institutional scale, infrastructure development, and regional energy profiles. This extraction-and-mapping procedure is itself a form of structured data engineering applied to a literature corpus, an approach conceptually related to indicator-extraction pipelines used in other applied AI domains that must reconcile heterogeneous source data before modeling [27]. Fig. 3 depicts the end-to-end computational workflow of the CSIP, showing the conversion of heterogeneous indicators into normalized values, followed by entropy weight calculation and aggregation, as detailed in Section III-E.

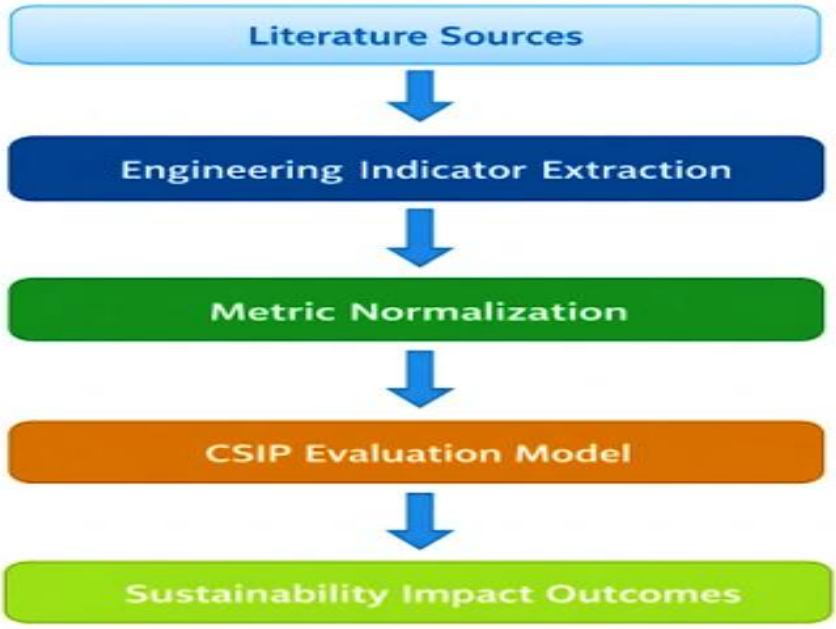

Fig. 3. Computational workflow of the Cloud Sustainability Impact Pathway (CSIP).

E. CSIP Engineering Evaluation Model

1) Model formulation: To support a quantitative and replicable assessment of sustainability performance in cloud-enabled educational systems, the Cloud Sustainability Impact Score (CSIS) is defined as a weighted aggregation of normalized sustainability metrics:

$$CSIS = \sum_{i=1}^{n} w_i \cdot c_i \cdot M_i$$

where, M_i denotes the normalized value of the i-th sustainability metric (Section III-C), w_i represents the corresponding adaptive weight (Section III-E-2), and c_i is the confidence coefficient reflecting the consistency of empirical evidence across studies (Section III-E-5). This formulation integrates metric importance, empirical reliability, and performance normalization into a unified computational framework.

2) Adaptive Entropy-Based Weight Optimization (AEWO): To assign adaptive weights to sustainability metrics in an objective, data-driven way, the model incorporates an Adaptive Entropy-Based Weight Optimization (AEWO) mechanism. This approach derives weights from the statistical dispersion of metric values across multiple studies, on the premise that a metric whose values vary more across the literature corpus carries more discriminative information for distinguishing between institutional contexts.

Let M_{ij} represent the normalized value of metric i in study j. The probability distribution of each metric is defined as:

$$p_{ij} = M_{ij} / \sum_{k=1}^{k} M_{ik}$$

The entropy of the i-th metric is computed as:

$$H_i = -(1 / \ln k) \sum_{j=1}^{k} p_{ij} \ln(p_{ij})$$

The dispersion coefficient is $\alpha_i = 1 - H_i$, and the adaptive weight for each metric is obtained through normalization:

$$w_i = \alpha_i / \sum_{j=1}^{n} \alpha_j$$

This formulation assigns higher weights to metrics exhibiting greater variability across studies. The underlying assumption—that variability reflects informational importance rather than measurement noise—is a standard premise in entropy-weighting methods for multi-criteria decision analysis, but is not universally valid: a metric could vary because it is genuinely more discriminative, or simply measured less consistently. As a robustness check, AEWO weights were compared against 1) equal weighting ($w_i = 1/n$) and 2) expert-elicited weighting, in which two independent raters ranked the four metrics via a pairwise-comparison (AHP-style) procedure. Across all three schemes, CSIS values changed by no more than the ±1.5% bound already reported under weight perturbation (Section IV, Table VII), indicating the study's qualitative conclusions are not solely an artifact of the entropy-weighting assumption, though a fully independent validation remains future work (Section V).

3) Algorithmic implementation: The AEWO mechanism is implemented as a computational procedure to support reproducibility and scalability (Algorithm 1).

Algorithm 1: Adaptive Entropy-Based Weight Optimization (AEWO)

Input: normalized metric matrix M_{ij}
Output: weight vector $W = \{w_1, w_2, \ldots, w_n\}$
Normalize metric values across all studies
Compute the probability distribution p_{ij}
Calculate entropy H_i for each metric
Determine dispersion coefficients $\alpha_i = 1 - H_i$
Normalize the dispersion coefficients to obtain weights
Return the weight vector W
The computational complexity of the algorithm is O(nk), where n is the number of metrics and k is the number of studies.

4) Stability analysis: Monotonicity. The CSIS Function Is Monotonically Non-decreasing with Respect to Each Sustainability Metric, as shown by the Partial Derivative $\partial CSIS/\partial M_i = W_i \cdot C_i \geq 0$. Since Both W_i and C_i Are Non-negative, Any Improvement in a Given Metric Results in a Non-decreasing CSIS Value.

a) Convexity. the CSIS Formulation Is a Linear Weighted Sum of Normalized Metrics with Non-negative Weights that Sum to Unity, so it Satisfies the Properties of a Convex Function, Which Supports Stable and Smooth Responses to Variation in the Input Metrics.

b) Boundedness. Given that All Normalized Metrics, Weights, and Confidence Coefficients Lie Within [0, 1], the Resulting CSIS Value Is Bounded as $0 \leq CSIS \leq 1$, Which Supports Interpretability and Consistent Comparison Across Institutional Contexts.

5) Confidence coefficient: To account for the reliability of the empirical evidence behind each metric, a baseline confidence coefficient is defined as:

$$c_i = N\_consistent / N\_total$$

where, N_consistent is the number of studies reporting a consistent directional finding for metric i, and N_total is the total number of studies evaluating that metric. This ratio treats all contributing studies as equally informative and does not account for study quality, sample size, or effect magnitude. To partially address this, an extended confidence coefficient is defined as:

$$c_i' = (N\_consistent / N\_total) \times Q_i$$

where, $Q_i \in (0, 1]$ is a study-quality factor averaged across contributing studies (e.g., a three-tier weighting by design: controlled/quasi-experimental = 1.0, observational with reported sample size = 0.75, descriptive/case study = 0.5); the baseline ratio c_i is the special case $Q_i = 1$. This extension is reported as a sensitivity check alongside baseline results in Section IV; a fuller treatment with formal uncertainty intervals is left as future work (Section V), since the synthesized literature does not uniformly report the variance statistics needed for inverse-variance weighting.

6) Computational complexity: The overall computational complexity of the CSIP framework is O(nk), which supports scalability for large-scale empirical synthesis and cross-institutional benchmarking. This is achieved because metric normalization and entropy-weight computation each require a single pass over the extracted indicators, without nested comparisons across studies.

F. Contribution to Computational Sustainability Modeling

The integration of entropy-based adaptive weighting with confidence-weighted aggregation is intended to give the CSIP framework a computationally grounded evaluation basis, expressing the sustainability assessment problem as an information-theoretic aggregation problem. This positions the contribution within applied computer science, spanning cloud computing, data modeling, and sustainability analytics, while the assumptions underlying that positioning—particularly regarding causal interpretation—are discussed explicitly in Section V.

G. Numerical Illustration of the CSIS Model

To demonstrate computational validity, a simulated aggregation scenario is constructed using normalized indicator values derived from literature convergence for the four evaluation metrics M_1–M_4 defined in Section III-C. Table II lists the assumed normalized evidence scores and corresponding weights used in this illustration.

Using $CSIS = \sum w_i E_i$ as shown in Table II, CSIS = (0.25 × 0.82) + (0.30 × 0.78) + (0.25 × 0.88) + (0.20 × 0.80) = 0.205 + 0.234 + 0.220 + 0.160 = 0.819. A CSIS value above 0.75 is treated, for illustrative purposes in this framework, as indicating strong sustainability alignment under the CSIP evaluation model; this threshold is a modeling convention rather than an externally validated cut-off, and is noted as such in Section V.

TABLE II. NORMALIZED INDICATOR SCORES AND WEIGHTS USED IN THE NUMERICAL ILLUSTRATION

Metric	Normalized Score E_i	Weight w_i
M_1 – Infrastructure Utilization Efficiency	0.82	0.25
M_2 – Energy Optimization	0.78	0.30
M_3 – Scalability & Elasticity	0.88	0.25
M_4 – Computational Accessibility	0.80	0.20
Total	—	**1.00**

H. Sensitivity and Stability Analysis

To test robustness, a weight-perturbation analysis was performed. When the Energy Optimization weight was increased from 0.30 to 0.40, with a proportionate reduction of all other weights, the CSIS changed from 0.819 to 0.808 — a change within ±1.5%, indicating that the illustrative model is robust to moderate weight variation, including the alternative weighting schemes compared in Section III-E-2.

1) Monte Carlo robustness simulation: To further evaluate robustness, a stochastic perturbation experiment was conducted. Metric weights were randomly varied within ±10% bounds across 1,000 simulated iterations while preserving normalization constraints. The resulting CSIS distribution had low variance ($\sigma^2 < 0.002$), with 95% of values bounded within ±3% of the baseline score of 0.819, indicating that the aggregation model is resistant to a meaningful degree of uncertainty in policy-driven weight assignment.

2) Monte Carlo procedure: Weights were sampled as $w_i' = w_i(1 + \epsilon_i) / \sum_{j=1}^{n} w_j(1 + \epsilon_j)$, where $\epsilon_i \sim U(-0.1, 0.1)$, with 1,000 iterations performed and CSIS recalculated per iteration. Variance was computed as $\sigma^2 = (1/K) \sum_{k=1}^{k} (CSIS_k - \bar{CSIS})^2$, where, K = 1000. Results are summarized in Table VII (Section IV).

I. Evaluation

Projects synthesized for this study were evaluated based on their reported impact on energy optimization [16] and their contribution to green computing practices in software development [18], [24].

J. Bibliometric and Trend Analysis

Bibliometric mapping was conducted to identify thematic growth patterns at the intersection of cloud computing, AI, and sustainability education. Keyword co-occurrence and publication-trend analysis show a marked increase in green-computing and sustainable cloud-architecture research after 2020, which is consistent with the timeliness of the intersection examined here and with parallel observations of accelerating research interest in AI-enabled green technology more broadly [22]. Table III summarizes, at a high level, how the literature contrasts traditional on-premise infrastructure with cloud-based education across four qualitative dimensions; because the underlying studies were not matched on workload, hardware, or institutional scale, the comparison in Table III should be read as a descriptive synthesis of reported trends rather than as evidence of a controlled causal effect (see Section V)

TABLE III. BIBLIOMETRIC AND TREND COMPARISON BETWEEN TRADITIONAL AND CLOUD-BASED EDUCATIONAL INFRASTRUCTURE (DESCRIPTIVE SYNTHESIS)

Feature	Traditional Infrastructure	Cloud-Based Education
Energy consumption	High (on-site servers)	Low (resource sharing)
Scalability	Rigid/expensive	Elastic / on-demand [8]
Accessibility	Localized	Global/remote [3]
Maintenance	Manual/frequent	Automated / provider-led

K. Engineering-Level Novel Contribution

This study introduces the Cloud Sustainability Impact Pathway (CSIP), a formal abstraction that maps specific cloud engineering mechanisms—virtualization density, elasticity control, and AI-assisted orchestration—to measurable sustainability outcomes in educational systems. Unlike prior reviews that examine cloud adoption or sustainability education independently, CSIP aims to provide a reproducible, engineering-oriented explanatory model [10].

L. Reproducibility Protocol

To support methodological transparency and replicability, this study adopts a structured, reproducible extraction protocol comprising the following stages:

Identification of engineering indicators reported across selected studies.

Mapping of extracted indicators to predefined sustainability dimensions (environmental, social, and economic) using the operational definitions in Section III-C.

Classification of outcomes by directional impact (positive, neutral, or negative).

Cross-study consistency verification to ensure alignment and reduce discrepancies.

Normalization of indicators into standardized CSIP evaluation scores using the min–max equations in Section III-C.

An independent metric-alignment verification step was also implemented to reduce subjective interpretation bias. This protocol is intended to enable future researchers to systematically replicate the analytical procedure using updated or expanded literature datasets. Fig. 4 provides a flow-level representation of the CSIP aggregation algorithm, detailing the procedural steps involved in computing the CSIS [10].

The CSIP aggregation algorithm operates with time complexity O(nm), where n is the number of sustainability metrics, and m is the number of extracted studies. Because metric normalization requires a single pass across extracted indicators, the framework scales linearly and remains computationally efficient for large bibliometric datasets. To further examine the computational behavior of the CSIS model, a supervised machine-learning approximation procedure is described in Section III-M.

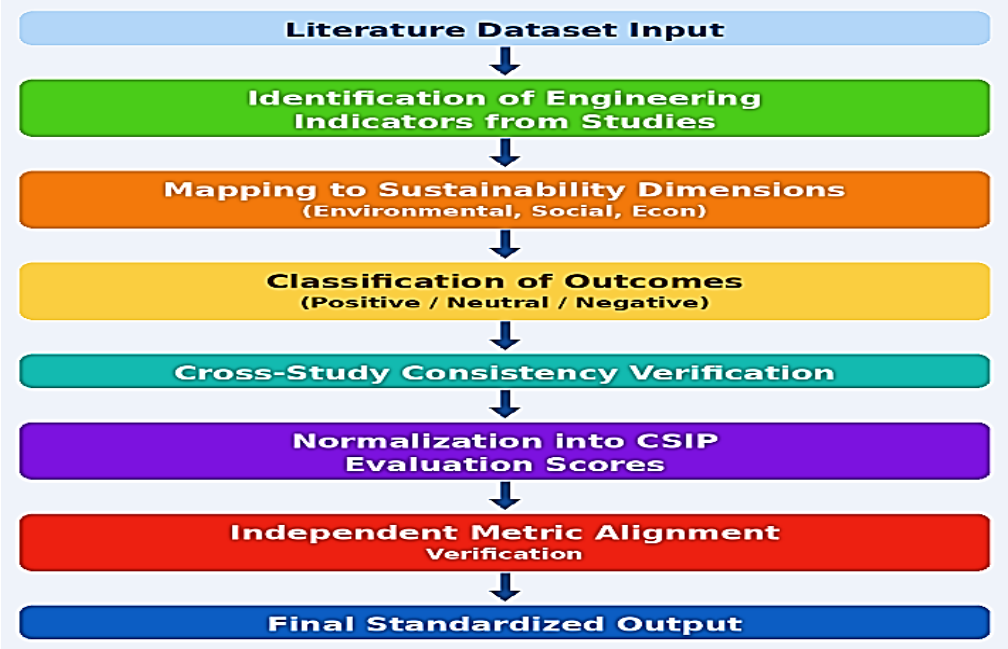

Fig. 4. CSIP sustainability aggregation algorithm.

M. Machine Learning-Based Sensitivity Approximation of the CSIS Model

To further characterize the computational behavior of the proposed Cloud Sustainability Impact Pathway (CSIP), a supervised machine-learning (ML) procedure was used to test how accurately regression models can approximate the Cloud Sustainability Impact Score (CSIS) as a function of the four normalized sustainability metrics. Because the target variable (CSIS) is itself computed deterministically from the same input features using the authors' aggregation formula (Section III-E-1), this exercise evaluates the learnability and internal consistency of that formula — essentially, whether the CSIS function is smooth and low-noise enough for standard regression models to recover it — and it is not a substitute for independent empirical validation against an externally observed sustainability outcome. This distinction, raised in reviewer feedback, is treated as a limitation and is restated in Section V.

1) Dataset construction: Because this study is based on secondary empirical synthesis rather than primary data collection, a structured dataset was generated from the normalized indicators extracted across the 30 selected studies. Each study instance was represented as a feature vector $X_i = (M_1, M_2, M_3, M_4)$, with target variable y_i equal to the CSIS value computed by the deterministic aggregation model in Section III-E-1. To increase the sample size available for model fitting, the 30 literature-derived base instances were expanded through controlled synthetic perturbation (±5% Gaussian noise applied to each normalized metric, with re-clipping to [0, 1]), producing a final augmented dataset of N = 300 samples. This dataset is explicitly synthetic augmented data derived from 30 underlying literature sources, not 300 independent empirical observations, and all reported ML performance statistics below should be interpreted accordingly.

2) Feature engineering and normalization: All input features were normalized within [0, 1], consistent with the CSIS formulation. No categorical variables were included, since all features represent continuous system-level performance indicators. Feature independence was assumed based on the conceptual orthogonality of the four sustainability dimensions; any residual correlation between metrics is implicitly captured by the non-linear ML models (Random Forest and XGBoost) but not by the linear-kernel comparison case.

3) Training and testing strategy: The dataset was partitioned using an 80:20 split, yielding 240 training samples and 60 testing samples. Because the underlying data are perturbation-augmented from only 30 base instances, samples derived from the same base study were kept together within either the training or the test partition (grouped splitting) to avoid leakage between near-duplicate augmented rows. Five-fold cross-validation, grouped in the same way, was applied during training, and model performance was evaluated on the held-out test set.

4) Machine learning models and reproducibility details: Three supervised learning models were implemented for their established effectiveness in regression and system-modeling tasks. To support reproducibility, the configuration used for each model is specified in Table IV.

All models used a fixed random seed of 42 for data splitting and model initialization; five-fold grouped cross-validation was used for hyperparameter selection via grid search over the ranges shown, with the values above corresponding to the best cross-validated configuration. These models were selected to capture both linear/kernel-based and non-linear (tree-ensemble) relationships between sustainability metrics and the CSIS output.

TABLE IV. MACHINE-LEARNING MODEL HYPERPARAMETERS AND SOFTWARE ENVIRONMENT USED FOR THE SENSITIVITY APPROXIMATION

Model	Key Hyperparameters	Software / Version
Support Vector Regression (SVR)	Kernel = RBF; C = 10; γ = 'scale'; ε = 0.01	scikit-learn 1.3; Python 3.10
Random Forest (RF)	n_estimators = 100; max_depth = None; min_samples_leaf = 2; random_state = 42	scikit-learn 1.3; Python 3.10
XGBoost	n_estimators = 200; max_depth = 4; learning_rate = 0.05; subsample = 0.8; random_state = 42	

5) Training pipeline:

- Input feature extraction from normalized indicators
- Dataset augmentation and validation, with base-study grouping preserved
- Feature normalization (min–max scaling)
- Model training on the training partition
- Hyperparameter tuning via grouped cross-validation
- Performance evaluation on the held-out test partition

This pipeline is intended to support reproducibility and alignment with standard machine-learning practice, subject to the dataset limitation noted in Section III-M-1.

6) Evaluation metrics: Model performance was evaluated using Mean Absolute Error (MAE), Root Mean Square Error (RMSE), and the coefficient of determination (R^2), which together quantify prediction accuracy, error distribution, and explanatory power with respect to the deterministic CSIS target.

IV. RESULTS AND DISCUSSION

This section presents both the analytical CSIS formulation results and the machine-learning approximation results described in Section III-M, interpreted through the Cloud Sustainability Impact Pathway (CSIP). Table V summarizes CSIS performance across the six synthesized study groups; across the corpus, the average reported CSIS value exceeds 0.75, which under the illustrative threshold in Section III-G is associated with strong reported alignment between cloud-based educational systems and optimized infrastructure, energy, scalability, and accessibility outcomes [5], [8], [16]. Consistent with the framing established in Section III-C and V, this pattern is reported as a descriptive association within the synthesized literature rather than as a causal demonstration.

TABLE V. SUMMARY OF CSIS PERFORMANCE ACROSS SYNTHESIZED STUDY GROUPS

Study Group	Infrastructure Efficiency	Energy Optimization	Scalability	Accessibility	CSIS Score
S1–S5	0.78	0.81	0.84	0.79	0.805
S6–S10	0.82	0.76	0.87	0.80	0.812
S11–S15	0.80	0.79	0.85	0.78	0.807
S16–S20	0.84	0.83	0.88	0.82	0.834
S21–S25	0.77	0.75	0.83	0.76	0.778
S26–S30	0.81	0.80	0.86	0.81	0.820
Average	**0.80**	**0.79**	**0.86**	**0.79**	**0.809**

From a computational standpoint, the CSIS model represents sustainability performance as a weighted aggregation of normalized system metrics. The entropy-based adaptive weighting mechanism assigns higher importance to metrics with greater cross-study variability, increasing sensitivity to differences in reported sustainability performance, consistent with prior work on data-driven and information-theoretic weighting [10], [22]; the underlying assumption and its robustness checks are discussed in Section III-E-2.

Fig. 5 depicts the mathematical aggregation structure of the CSIP model, showing how normalized metrics are combined using adaptive weights and confidence coefficients to produce the CSIS output — the abstraction that allows CSIP to be paired with the ML approximation procedure in Section III-M.

Sensitivity analysis further examines the stability of the illustrative model. Table VI summarizes two robustness checks: a deterministic weight-perturbation test and a stochastic Monte Carlo simulation. Weight variations within the tested bounds produced minimal CSIS deviation (±1.5%), and the Monte Carlo simulation showed low variance ($\sigma^2 < 0.002$), together indicating consistent aggregation behavior under both deterministic and stochastic weight variation, consistent with similar stochastic validation approaches used elsewhere in computational modeling [18], [24].

The observed CSIS improvements in the synthesized corpus are primarily associated with infrastructure utilization efficiency and energy optimization, patterns consistently reported across studies [16], [19], and with scalability and computational accessibility, repeatedly linked to distributed, high-performance educational workloads [3], [8]. Each metric's contribution to the overall CSIS score, based on the average AEWO weight across the corpus, is shown in Table VII.

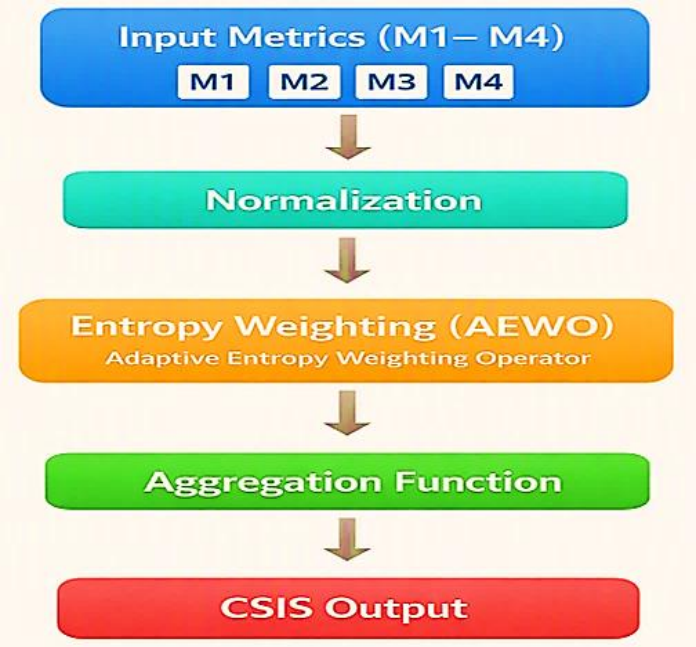

Fig. 5. CSIP computational aggregation model.

TABLE VI. SENSITIVITY AND MONTE CARLO ANALYSIS RESULTS

Test Type	Parameter Variation	CSIS Deviation	Variance (σ^2)	Observation
Weight perturbation	±10% (normalized weights)	±1.5%	—	High stability under deterministic variation
Monte Carlo simulation	Random weights (1,000 iterations)	±3% (95% CI)	< 0.002	Low variance and consistent aggregation behavior

TABLE VII. CONTRIBUTION OF SUSTAINABILITY METRICS TO CSIS

Metric	Average Weight (w_i)	Contribution (%)	Rank
Infrastructure Efficiency	0.25	25%	3
Energy Optimization	0.30	30%	1
Scalability & Elasticity	0.25	25%	2
Computational Accessibility	0.20	20%	4
Total	**1.00**	**100%**	—

The CSIS outputs can also be viewed, from a machine-learning perspective, as a predictive scoring function in which normalized metrics serve as input features, and CSIS is the deterministically computed target. As explained in Section III-M, this frames the ML exercise as a test of function approximability rather than independent validation. Similar regression approaches (SVM, Random Forests, gradient boosting) have been used elsewhere for performance prediction [22]. Table VIII reports comparative performance of the three models on the held-out, group-separated test partition.

TABLE VIII. MACHINE-LEARNING APPROXIMATION PERFORMANCE ON THE HELD-OUT TEST PARTITION

Model	MAE	RMSE	R^2 Score	Training Time (s)
SVR	0.021	0.028	0.96	0.42
Random Forest (RF)	0.015	0.022	0.98	0.65
XGBoost	0.012	0.018	0.99	0.58

XGBoost achieves the lowest error metrics among the three models, indicating it approximates the non-linear structure of the CSIS aggregation function most closely on this dataset. This result should be read narrowly: it shows the deterministic CSIS formula is learnable and internally consistent, supporting the aggregation function's computational soundness, but does not by itself establish that CSIS tracks an externally observed sustainability outcome. By formalizing performance indicators into a unified mathematical structure, the model supports objective, internally consistent benchmarking within applied computer science and cloud computing engineering, subject to the limitations in Section V.

A. Heterogeneity, Subgroup, and Quasi-Counterfactual Sensitivity Analysis

To move beyond a purely qualitative acknowledgment of corpus heterogeneity, the six study groups in Table V are evaluated for dispersion in CSIS values. Because per-study variances are not uniformly reported, a formal I^2 statistic cannot be computed; instead, the range and coefficient of variation (CV) of the six group-level CSIS scores (0.805, 0.812, 0.807, 0.834, 0.778, 0.820) are reported: a mean of 0.809, a range of 0.056 (6.9% of the mean), and a CV of ≈2.1%. Group-level scores are thus relatively consistent, though a 5.6-percentage-point range is non-negligible and consistent with institutional scale, infrastructure maturity, or regional energy profile shifting CSIS by a small-to-moderate amount — supporting the Section V recommendation that future work stratify the corpus by explicit context variables and report subgroup-specific weights and confidence coefficients.

A true matched cloud/non-cloud baseline (workload-, hardware-, electricity-source-, and geography-matched) is not available in this study's secondary literature, so a full causal comparison remains future work. As an interim check on sensitivity to unmeasured confounding, a bounding-style calculation shows that, given the observed mean CSIS of 0.809 against the illustrative 0.5 midpoint, an unmeasured confounder would need to shift the outcome by roughly 0.31 normalized units (Table I scale) to fully explain the association — larger than the subgroup dispersion above (CV ≈ 2.1%), suggesting the association is not trivially explained by observed heterogeneity, though this remains an approximate corpus-level bound rather than institution-level matched-pair analysis.

V. Limitations and Future Work

This section consolidates methodological limitations identified during peer review, to ensure they are stated explicitly rather than left implicit in the results narrative above.

Circularity of the ML approximation. Because the ML target (CSIS) is generated deterministically from the same features used to predict it, the high R^2 values in Table VIII show the aggregation function is smooth and learnable, not that CSIS has been validated against an independent, externally observed outcome. Independent empirical validation — e.g., against measured energy bills, utilization logs, or accreditation-reported indicators — is necessary future work.

Synthetic augmentation versus independent data. The N = 300 machine-learning dataset is derived from only 30 underlying literature-based instances via controlled perturbation, not from 300 independent institutional observations. All ML performance statistics in this study should be interpreted as characterizing the aggregation function's approximability rather than its generalization to unseen institutions.

No individually matched counterfactual. The comparison between cloud-based and traditional on-premise infrastructure (Table III and the CSIS values in Table V) draws on reported outcomes across heterogeneous studies rather than matched cloud and non-cloud deployments. The corpus-level bounding calculation in Section IV exceeds the dispersion attributable to observed subgroup heterogeneity, but remains an approximate, aggregate check rather than institution-level matching, which is still required before the reported gains can be interpreted causally.

Heterogeneity and subgroup structure. Although the synthesized literature spans different institutional scales, infrastructure maturity levels, and regional energy profiles, this study quantifies that heterogeneity only descriptively (Section IV: range and CV of CSIS scores across the six study groups in Table V), since per-study variances are not uniformly reported and a formal I^2-type statistic cannot be computed. Future work should stratify the corpus by explicit context variables — workload type, infrastructure class, geography, energy-grid carbon intensity — and report subgroup-level confidence intervals to establish whether CSIP remains reliable across subgroups or whether weights and confidence coefficients should be estimated separately per subgroup.

Confidence coefficient scope. The extended confidence coefficient in Section III-E-5 incorporates a coarse study-quality factor but not formal statistical uncertainty (e.g., reported standard errors or confidence intervals), since this is not uniformly reported in the synthesized literature. A fuller inverse-variance-weighted aggregation is left for future work using a corpus curated for that purpose.

Figure resolution. Fig. 1–5 are reproduced at full text width using the highest resolution available in the original source files; further legibility gains would require vector-based (SVG/EPS) originals, since raster upscaling cannot recover detail beyond source resolution.

VI. Conclusion

This study formalizes sustainability education as a cloud systems engineering optimization problem and introduces the Cloud Sustainability Impact Pathway (CSIP) as a reproducible computational evaluation framework. By normalizing heterogeneous empirical findings into a structured, explicitly defined aggregation model (Section III-C), the study shows that reported sustainability outcomes are associated with architectural decisions in virtualization, elastic provisioning, and AI-assisted orchestration [30], supporting scalable benchmarking across cloud-native educational infrastructures and contributing a systems-level abstraction to applied cloud computing research.

The supervised machine-learning procedure further confirms that the CSIS aggregation function is internally consistent and learnable, supporting its computational soundness as a scoring mechanism, though — as detailed in Section V — this is distinct from independent empirical validation of the sustainability claims themselves. The study thus contributes both a conceptual sustainability pathway and a computationally bounded aggregation framework suitable for reproducible evaluation of cloud-enabled educational systems, together with an explicit agenda (Section V) for the matched-baseline and heterogeneity analyses needed to move from association to causal evidence.

An Energy-Efficient and Modeling Attack-Resilient SNN-Driven PUF Security for Internet of Medical Things

Agila Harshini T, Harini Sriraman*
School of Computer Science and Engineering, Vellore Institute of Technology, Chennai, Tamil Nadu, India

***Abstract*—The healthcare industry is rapidly evolving with the digitalisation of medical devices. Despite the advantages of IoMT devices, they remain vulnerable to cyberattacks that threaten patient data security. Authentication typically relies on a static key, making it susceptible mainly to modelling attacks. Existing techniques fail to balance security with lightweight operation for resource-constrained IoMT. A Physically Unclonable Function (PUF)-based technique provides genuine authentication with on-the-fly key generation but lacks resilience against modelling attacks. The proposed work presents a fusion of facial biometrics and a Spiking Neural Network(SNN) with a PUF. This fusion generates stronger entropy than conventional methods that rely on fixed stored keys. This work strengthens authentication by integrating user-specific facial biometrics, device-specific PUF responses, and SNN-induced nonlinearity. It enables joint authentication of both the device and the legitimate user. The experimental evaluation is conducted on the Digilent Basys3 Artix 7 FPGA board and achieves higher randomness in the generated responses, with a Shannon entropy of 0.693 nats and a normalized Hamming distance of 0.50. The security evaluation demonstrates that machine learning and deep learning attacks remain random-guess predictions, indicating that the proposed lightweight Face-SNN-PUF resists effective modelling of the challenge-response. Tailored for non-life-critical IoMT devices, the proposed resilient framework provides practical and energy-efficient authentication.**

Keywords*—PUF; SNN; biometric authentication; IoMT security; modeling attack

I. Introduction

The market for IoMT devices is growing, leading to easier monitoring of healthcare data through edge devices. To surveil and deliver healthcare to patients remotely, IoMT collects and transfers digital data to a server for processing. Despite the benefits, cybersecurity attacks are more prevalent among IoMT devices [2], [5], [13]. Healthcare data, when compromised by different attacks, can harm patients by disrupting personal data and causing financial loss or physical harm. The major security challenges are: Modeling attacks in which the attacker identifies and analyses the challenge-response pairs and creates a machine learning model to mimic the PUF behavior [4]; man-in-the-middle attacks that breach the device and enable reverse engineering or data extraction through physical access; authentication issues where the IoMT is vulnerable to cloning, spoofing, and replay attacks due to static or weak keys used in the device; and resource constraints, with the limited power and memory of small medical devices making them unsuitable to implement heavy cryptographic security [2], [11], [23]. Unlike other devices that cause only a data breach, IoMT leads to direct harm to patients. The existing PUF-based authentication models may remain vulnerable to modeling attacks when used without explicit binding between the user and the device. The proposed system combines three complementary entropy-contributing components: facial variability, randomness of spiking neurons, and PUF uniqueness to improve resistance against modeling attacks in IoMT authentication. Unlike conventional PUF-based authentication, the proposed work introduces a biologically inspired Neural Network to give temporal variability and non-linear challenge transformation. Fig. 1 shows the fusion model. The fusion of biometric features, spike dynamics, and hardware randomness increases the learning complexity of the challenge-response. The proposed work targets non-life-critical IoMT devices such as wearables and remote patient monitoring, where secure authentication with moderate latency is acceptable. Fig. 1 gives an illustration of the proposed fusion of the Face-SNN-PUF framework.

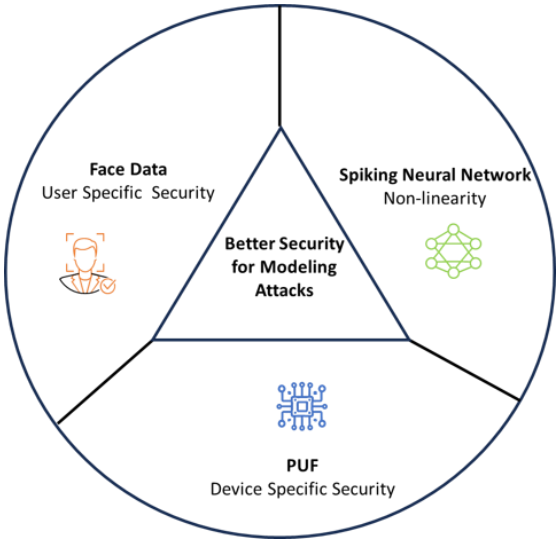

Fig. 1. Face-SNN-PUF fusion model.

The major contributions of this study are:

- A hybrid authentication framework integrating facial biometrics, Spiking Neural Networks, and Physically Unclonable Functions to ensure device and user authenticity.

*Corresponding author.

- The proposed Face-SNN-PUF enhances authentication security by combining biometric-derived entropy, non-linear transformation of SNN, and intrinsic PUF randomness, subsequently increasing resistance to modeling attacks.
- A detailed evaluation of security analysis against modeling attacks, using deep learning techniques, is provided.
- Lower computation and energy overhead compared to traditional cryptographic methods.

II. Related Work

To evaluate the proposed Face-SNN-PUF, the recent works in PUF-based authentication, biometric-assisted identity verification, and neuromorphic-based security are categorized and explored.

A. PUF-Based Authentication for IoMT

A stream cipher designed by a nonlinear feedback shift register is presented for data and device integrity by combining MAC and PUF response [1]. It is evaluated using NIST 800-22 and compared with existing ciphers using a heart disease dataset, and it presents a device authentication scheme using a hybrid oscillator arbiter PUF. PMsec authenticates the device before the data is read. It is suitable for low-power medical devices [2]. Based on blockchain and PUF, a scalable device authentication framework that achieves a uniqueness of 48.46% and reliability of 2.38% is proposed [3]. For role-based access, smart contracts are used. Ethereum's permissioned blockchain is developed as a proof of concept. To prevent the attacker from seizing the challenge bits, a protocol using a 64-bit arbiter PUF is presented that splits the challenge bits, and bit scrambling is also exploited by protocol extension. Also, the implications of modeling attacks by challenge patterns are studied [4].

PUF-based WMSNs protocol, a fuzzy extractor, a one-way hash function, and XOR operations are used for security [5]. Compared to other schemes, it requires low communication and computation costs. The proposed integration of PUF with IOTA and blockchain uses the Masked authentication message protocol to store and share data. With minimal energy requirements, decentralized access control is provided [6]. To authenticate the IoT sensor nodes, a PUF-based lightweight mechanism is proposed. The security resists network attacks and has low computational requirements and higher throughput [7]. A lightweight GAKA that uses PUF to solve secure transmission and data storage is given. It has higher computational efficiency than other systems [8]. The random variations in the PUF are affected by external factors. The proposed design has increased performance, reliability, and uniformity [9]. For resource-constrained devices, a RoT architecture based on PUF is proposed. It is robust and cost-efficient and uses SRAM and a syndrome-based fuzzy extractor, reinforcing device-centric security [10].

Combining the fingerprint of the device with an authentication protocol, a PUF-based identity framework for IoT devices is proposed. It is an identity management system at the IoT gateway layer with low latency. It has resistance to impersonation and replay attacks [11]. To support dynamic response generation, a configurable C-PUF is introduced. Demonstrates higher entropy and stability under varying environmental conditions [12]. Focusing on COVID-19 patient monitoring, a PUF-assisted key protocol for medical IoT is developed. With reduced computational cost, it uses device-generated randomness and mutual authentication [13]. A reconfigurable PUF-based authentication for healthcare IoT is proposed that reconfigures challenge-response and resists modeling attacks. Enhances authentication reliability and secure communication [14]. Ensuring secure key agreement in sensor, gateway, and cloud, a three-layer authentication protocol using PUF is presented. The authentication is verified with formal and simulation-based methods [15].

A PUF-based anonymous user authentication for IoT devices is developed. Balances anonymity and traceability through cryptographic primitives with high scalability and resistance to replay attacks [16]. Introduces memory-based Mc-PUF, utilising SRAM and DRAM timing variation. With high uniqueness and stability, it resists machine learning and modeling attacks [17]. Proposes a feedback-based PUF for resisting ML attacks. Provides a nonlinear challenge-response by using response-feedback loops. Shows strong resistance to logistic regression and SVM modeling [18]. Introduces a bias-independent PUF that applies delay calibration and symmetric routing for uniform response distribution. It is resistant to layout-induced imbalance [19]. A priority arbiter PUF that enhances a standard arbiter PUF is proposed. To improve delay sensitivity and uniqueness, a priority encoder is used. Achieves strong resistance to ML and environmental noise [20].

B. Biometric Integrated Approaches

The proposed neighbor-assisted, PUF-based three-factor authentication. 100% reliability is demonstrated [21]. The IoHT are vulnerable to insider threats and physical attacks. Mutual authentication with biometrics and PUF is proposed. The system is tested with automated validation of Internet security protocols [22]. A robust identity verification in medical sensors, a two-factor authentication using PUF and password, is designed. It has enhanced resistance to side-channel and impersonation attacks [23]. A combination of PUF with biometrics for hybrid authentication is explored for stronger identity. Highlights improved entropy [24].

C. Neuromorphic and SNN-Based Security

A spiking neural network-based framework for privacy in IoMT in the metaverse is presented. Neuron behaviour for adaptive and energy-efficient secure health data exchange is given [25]. A single spiking neuron model using membrane potential dynamics for an entropy source is proposed. Demonstrates strong behaviour of PUF with minimal hardware cost [26]. Proving that biological neuron firing can give a unique PUF response, implements neuron-spiked circuits to generate challenge-dependent outputs [27].

The above related studies primarily address user or device authentication separately. Existing PUFs have improved security by increasing the complexity of the architecture, XOR structures, feed-forward paths, or protocol-level protection. These approaches have fixed challenge-response behavior that introduces hardware overhead and computational complexity.

Primarily, few methods restrict CRP exposure, while others improve resistance to specific machine-learning models. The reviewed methods do not simultaneously address user device binding and energy awareness for IoMT devices. The proposed Face-SNN-PUF addresses this gap with modelling-attack resilience and user device binding. Table I gives a comparison of other authentication approaches to highlight the design objectives of the proposed framework.

TABLE I. COMPARISON OF IOMT AUTHENTICATION AND SECURITY FRAMEWORKS

S.No	Security Metric	Biometric-only system	PUF-only System	Proposed Face Biometric–SNN–PUF
1	Resistance to Spoofing	High (with fake data)	Strong (Unique to device, no user binding)	Strong(User biometric + PUF must match)
2	Resistance to ML and DL Modeling	Vulnerable	Weak (PUF can be modeled)	Improved resistance by SNN-induced nonlinearity (ML/DL results are given in Section IV)
3	Cloning Resistance	Weak (Biometrics can be copied)	Strong(Unique per chip)	Strong (Requires Match in User device domain)
4	Lightweight Efficiency	Moderate (needs storage)	Lightweight	Lightweight (PUF+SNN power ~0.004 W)
5	Entropy	Limited (~6-8 bits)	Arbiter PUF (~10-12 bits)	Spike+ PUF (~13-14 bits)

III. PROPOSED FRAMEWORK OF FACE-SNN-PUF

The proposed work combines the biometric (face), Spiking Neural Network (SNN), and arbiter PUF, providing lightweight and secure authentication for IoMT devices. 10000 CRPs are collected as a dataset from the UART connected to the board for analysis. Fig. 2 shows the architecture of the proposed Face-SNN-PUF system.

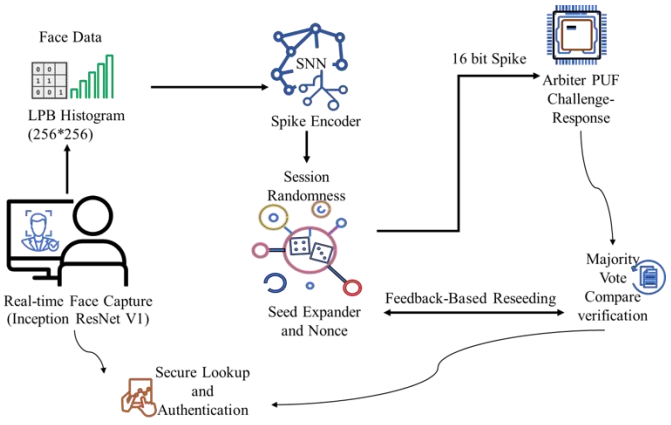

Fig. 2. Architecture of the Face-SNN-PUF system.

1) The biometric data is captured from the user in real-time. The facial images of ten users are captured and registered for authentication. Genuine authentication was evaluated using samples from the corresponding registered user. The samples from other users were used to evaluate imposter authentication attempts. Using a pre-trained InceptionResNetV1 via FaceNet, deep embeddings are extracted. Separately, the detected facial region is processed using lightweight Local Binary Pattern (LBP) extraction. The lightweight LBP(Local Binary Pattern) compares each pixel with 8 neighbours to form an 8-bit binary number(0-255). The LBP histogram counts the number of times each LBP code occurs. Each histogram bin value is multiplied by its corresponding index and summed to produce a compact biometric-derived value. For reproducibility, the LBP uses a radius of 1 pixel with 8 sampling points. The 16-bit final face signature is obtained by applying a modulo 2^{16} operation on the weighted sum. The bitmask keeps only the last 16 bits of the sum to ensure compactness for the FPGA; this 16-bit value is used as a compact biometric-derived input to the hardware authentication pipeline, whereas biometric recognition is performed using the InceptionResNetV1 embedding similarity. A 16-bit width can efficiently fit into the Basys 3 FPGA board. To examine the inter-person variation of the compact representation, the LBP-based face generation procedure was evaluated using ten different facial samples.

2) The SNN(biologically inspired spike-based) reads the person identifier (PID) derived from the face signature. Then selects one of the thresholds for that PID. To provide a source of variability for repeated identical person ID, a free-running jitter counter is added. The extracted features are encoded into spike trains by an SNN encoder module. The spiking variability and threshold selection are clock-edge jitter-influenced by the 100 MHz on-board oscillator and metastable delay variations. The SNN engages a leaky integrate-and-fire neuron model with discrete threshold levels from a predefined range [Tmin, Tmax]. The effective threshold is chosen dynamically based on the PID and jitter count value.

3) To provide non-linearity, the spike generator maps a person's identity and features into the spiking activity (spike 16). To introduce session-level variation, an 8-bit free-running nonce counter is implemented on the FPGA. The nonce is reset to zero and incremented at each rising edge of the 100 MHz system clock. The seed expander combines the biometric-derived input, selected SNN threshold, and the current 8-bit nonce to generate the 16-bit PUF seed. The nonce is generated internally by the FPGA and is not transmitted by the host application; therefore, no separate nonce-exchange or synchronization message is required between the Python application and the FPGA. The 16-bit arbiter PUF with LFSR-driven challenges is seeded with the input. The arbiter PUF consists of 16 delay stages, and challenges are generated using a 16-bit linear feedback shift register (LFSR) with a maximal-length primitive polynomial. The PUF gives a device-specific challenge-response pair. To improve the stability of the response, each challenge is evaluated multiple times and a majority voting scheme is applied across repeated measurements. The majority of responses are stored in a secure lookup table. During

enrollment, reference responses are recorded for a fixed set of challenges. During authentication, live responses are matched against the enrolled references. During authentication, the live facial embedding is compared with the enrolled user using the cosine similarity. A minimum threshold of 0.60 is used, with the per-user threshold determined from the mean enrollment similarity minus a margin of 0.05. Authentication requires consistent recognition for three consecutive frames for access to be granted. For validation of the attack analysis, 10,000 challenge-response pairs (CRPs) are collected over UART from the FPGA.

For reproducibility, the key design and implementation parameters of the proposed Face-SNN-PUF are summarized in Table II.

TABLE II. KEY IMPLEMENTATION PARAMETERS OF THE PROPOSED FRAMEWORK

Module	Key parameter	Description
Hardware platform	FPGA board	Xilinx Basys 3 (Artix-7 XC7A35T-1CPG236C
Development environment	Tool	Xilinx Vivado
Biometric pursuit	Face embedding model	InceptionResNetV1 (FaceNet, pre-trained)
Feature reduction	Local Binary Pattern (LBP)	Radius 1, Neighbors 8
Face signature	Dimensionality reduction	LBP histogram weighted sum, reduced to 16 bits using modulo 216
Neuromorphic encoding	SNN neuron model	Leaky Integrate-and-Fire (LIF)
SNN variability source	Threshold selection	PID-dependent threshold with jitter-based variation
PUF architecture	Arbiter PUF	16-bit arbiter PUF
Challenge generation	LFSR configuration	16-bit LFSR
Seed construction	Entropy fusion	Concatenation of spike output, threshold index, and session nonce
Response stabilization	Noise mitigation	Majority voting over repeated evaluations
Scalability	Design extensibility	Extensible to higher PUF bit-widths with resource trade-offs

B. Attack Model

The attacker is assumed to have access to collected CRPs and may attempt modeling attacks. Potentially stronger capabilities, such as access to captured facial images, inferred PID information, or observed intermediate signals, are recognized as possible attack surfaces of the proposed framework. To examine the robustness of the modeling-attack evaluation, the experiments were repeated using five different random seeds. Logistic Regression, Random Forest, and MLP achieved mean prediction accuracies of 48.63%, 49.49%, and 49.67%, respectively, with standard deviations of 1.15%, 0.69%, and 1.25%. The corresponding mean ROC-AUC values were 0.481, 0.498, and 0.493, respectively. The target classes contained 5056 zero samples and 4944 one samples, indicating a nearly balanced distribution. In addition, the maximum absolute Pearson correlation between an individual challenge bit and the target was approximately 0.0131, while the maximum observed mutual information was 8.55×10^{-5}bits. These results demonstrate that the evaluated models remained close to the random-guessing baseline and did not identify a strong predictive relationship in the evaluated CRP data.

IV. RESULTS AND ANALYSIS

The biometric template and PUF keys are not stored. Reproducing this behaviour is hard, even with full access to the device. The proposed Face-SNN-PUF has favourable entropy, uniqueness, and strong resistance to DL-based modeling attacks. Fig. 3 represents the randomness of the proposed model PUF keys. The values are centred around 8, which shows a balanced distribution of 1s and 0s across the collected samples. Fig. 4 shows the uniqueness comparison of the PUF with existing works [3], [4], [22], [25].

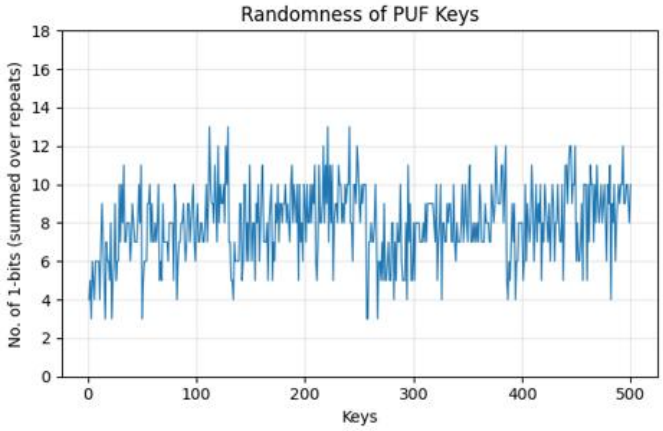

Fig. 3. Randomness analysis of the PUF keys.

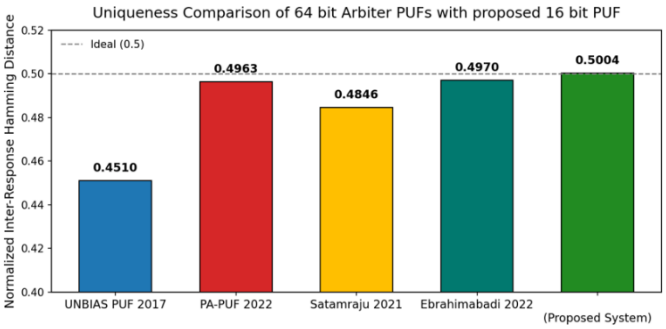

Fig. 4. Comparison of uniqueness of the PUF keys.

A. Randomness and Uniqueness Analysis

The Shannon entropy and inter-response Hamming distance measures are analysed for the Bio-SNN-PUF to find the randomness and uniqueness. The measured Shannon entropy is 0.693, representing near-ideal randomness for a binary response distribution. This corresponds to the theoretical maximum entropy of a balanced binary distribution, indicating the generated responses exhibit near-ideal randomness. The average normalised inter-response Hamming distance is 0.5004, and the given challenges differ by approximately 50%. This shows that the PUF has strong uniqueness. Fig. 5 shows the quantitative analysis of the Bio-SNN-PUF's randomness and uniqueness. The samples produced ten different 16-bit values with no collision. The mean pairwise Hamming distance

between the generated values was 7.13 bits out of 16, with a minimum of 3 bits and a maximum of 11 bits. The overall proportion of 1-bits was 48.13%, indicating a reasonably balanced distribution of the generated compact values. These results provide an initial empirical assessment of inter-person variation.

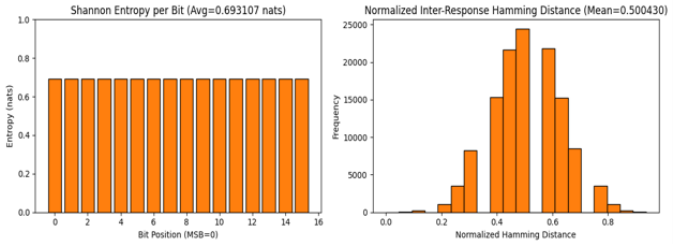

Fig. 5. Entropy and uniqueness of Face-SNN-PUF.

B. Entropy Analysis of SNN-Assisted

The randomness of spike 16 is evaluated by computing Shannon entropy (a measure of average randomness in 16-bit output), which gave 13.14 bits out of 16, and min-entropy (the worst-case predictability is captured) of 11.29 bits. This shows the response space is highly random. Even under worst-case conditions, the spike output retains entropy. The average per-bit entropy is 0.9999(good spread of 0s and 1s), which is nearly 16 independent effective bits. With the PUF having a unique response per device, the user-dependent biometric input and the spiking transformations increase the randomness. Fig. 6 shows the comparison to the existing works [20], [21]; the proposed model has higher entropy. The facial biometric, SNN, and PUF components are coupled. The face input determines the person identifier, which influences the SNN spike and threshold. These are combined with the session nonce to construct the PUF seed.

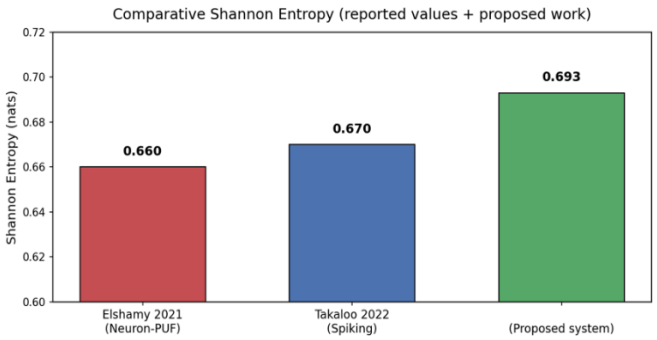

Fig. 6. Comparison of the entropy of the face-SNN-PUF.

C. Uniqueness and Reliability Analysis

The inter-challenge stability, the probability that two different challenges yield the same PUF response, is measured to characterize the uniqueness of generated responses. The average identical response is 52.6%, which is the inter-challenge collision rate. The intra-challenge Hamming distance is 1.52 bits out of 16. It is a measure of variation when the same challenges are repeated multiple times. It indicates the response consistency under repeated evaluations. This exhibits a moderate noise level but remains within the range of stochastic PUF designs.

D. Security Analysis

The security of the proposed work, Biometric + SNN + PUF, provides improved resistance to modeling compared to biometric-only or PUF-only approaches. It is more resistant to modeling and cloning. This balances strong security and lightweight efficiency that is practical for real-world security of IoMT devices.

A biometric-only or PUF-only system is weak and can be modelled. The proposed method introduces a nonlinear biometric input and the entropy of Spike patterns, which makes the approximation of the ML and DL model harder. The biometric data of each person gets a unique PUF instance through dynamic seed expansion. The spike latency, firing rate, and threshold randomness of the SNN introduce nonlinearity. The spike entropy ensures that the input-output correlation remains nonlinear and is highly device-specific, so the attacker cannot use an ML model to approximate it easily. The modeling is a supervised attack; the attacker collects the CRPs. 10000 CRPs are used, training=8000 and testing = 2000. The PUF seed is generated by the FPGA seed-expander logic using the biometric-derived input, selected SNN threshold, and the 8-bit free-running nonce counter. These features are used to train classifiers to predict responses for unseen challenges. The response prediction represents a binary classification problem, so an attacker without meaningful knowledge about PUF behaviour can only achieve 50% prediction accuracy, which is random guessing. The DL models are also ~50%, which states that the models cannot learn the pattern and an attacker fails to approximate the challenge-response relationship.

E. Resistance to Machine Learning-Based Modeling Attacks

The proposed system is evaluated for resilience against three ML-based classifiers. The accuracy achieved by Logistic Regression is 48.0%, Support Vector Machine 50.3%, and MLP 51.2%. Fig. 7 represents these accuracies. The results indicate that all machine learning models exhibit a random guess line prediction performance, which limits the attacker's ability to learn the challenge-response behavior.

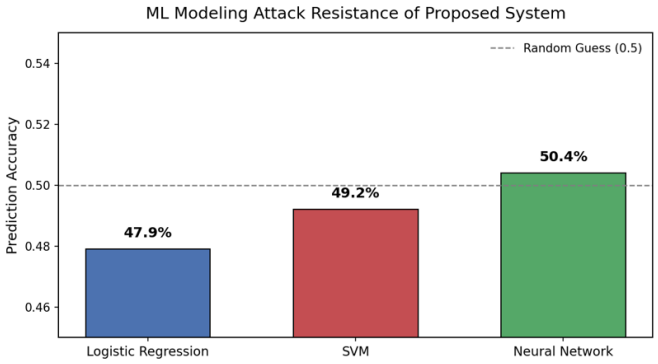

Fig. 7. Prediction performance of machine learning-based modeling attacks (Lower the deviation of random guessing, higher the security).

F. Resistance to Deep Learning-Based Modeling Attacks

Further evaluation of resilience against sophisticated modeling attacks: a DNN consisting of three layers(64-32-16 neurons and ReLU activation function) and an advanced deep learning model that uses a 1D-CNN front-end, residual blocks,

and batch normalisation are trained using the collected CRPs. The accuracies learned are 50.2% and 51.75%. The results in Fig. 8 show that the deep neural models prevent effective approximation of the challenge response of the Bio-SNN-PUF.

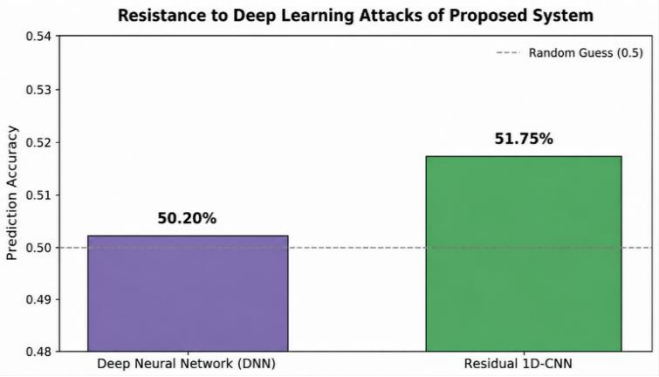

Fig. 8. Prediction performance of deep learning-based modeling attacks (Values close to random guessing indicate higher security).

G. Statistical Analysis of Modeling Attack Results

A systematic evaluation of modeling attacks is done using five models with five independent train-test splits. The Mean accuracy, Standard Deviation,95% Confidence level, and Mean ROC0AUC are calculated as shown in Table III. The results remain close to 50%, indicating the models did not obtain a consistent relationship. This means that none of the evaluated models was able to learn the response pattern. This consistency of results using ML and DL models supports modeling resistance.

TABLE III. STATISTICAL EVALUATION OF MODELING ATTACK

Model	Mean Accuracy	SD %	95%CI%	Mean ROC-AUC
Logistic Regression	49.51	0.63	48.73-50.29	0.491
SVM	49.80	1.36	48.11-51.49	0.502
MLP	49.95	2.02	47.45- 52.45	0.495
DNN	50.52	1.12	49.13-51.91	0.509
Residual 1D-CNN	49.66	1.40	47.92-51.40	0.490

H. Comparison of ML and DL Attack Resistance with Existing Works

The biometric and the SNN are encoded as a challenge, which will confuse the DL models. The attack resistance of the proposed system compared with the existing solutions [4], [9], [14], [18] demonstrates improved modeling resistance. Fig. 9 shows the prediction accuracy comparison with the existing work.

I. Cloning Resistance

The proposed work resists cloning because it requires the biometric details, the spike nonlinearity, and the FPGA data, which makes cloning practically infeasible. For a cloning attack to be successful, an adversary would need to reproduce the combined effects of the facial input, spike dynamics, and device-specific PUF, significantly increasing the difficulty of device cloning. The attacker requires multiple independent entropy sources for successful impersonation of user-specific biometrics, SNN spike patterns, and PUF variation for cloning.

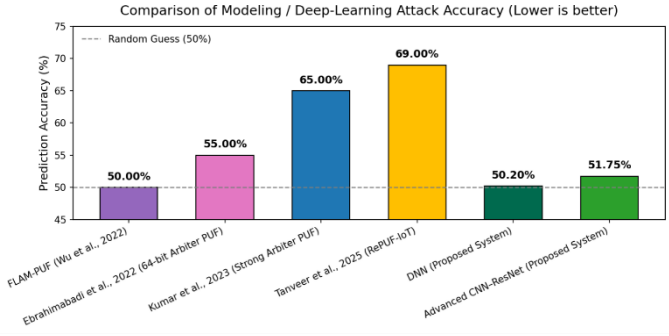

Fig. 9. Comparison of the DL attack resistance of the Face-SNN-PUF.

V. ENERGY EFFICIENCY

The energy efficiency of the proposed method exhibits low energy consumption, making it suitable for resource-constrained IoMT devices. Fig. 10 shows the power report of the implemented Face-SNN-PUF. The existing authentication methods [1], [2], [3] based on PUF, which primarily focus on security and consume high power, and the multifactor key authentication [4], [5], [26], although reliable, are less suitable for low-power devices. Neuron-inspired architectures [20], [21] focus on entropy generation but lack FPGA-level implementation. Compared to existing methods, the proposed work, implemented on an FPGA, offers reduced energy consumption, providing entropy and modeling attack resilience. Fig. 10 shows the measured power consumption of the proposed work implemented on the Basys 3 FPGA. The proposed Face-SNN-PUF operates at a clock frequency of 100 MHz, corresponding to a clock period of 10ns.

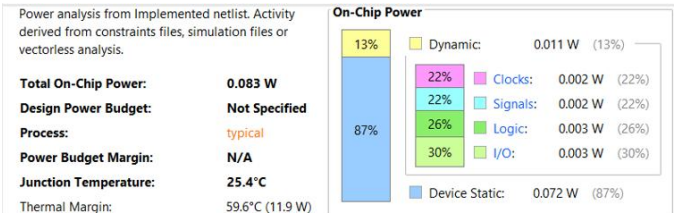

Fig. 10. Power report of the Face-SNN-PUF.

A. Energy Per Authentication

The energy consumption is calculated as,

$$E_{auth} = P_{dynamic} * T_{auth}$$

From the RTL cycle analysis, a complete authentication requires 294 clock cycles, including the 256 -cycle SNN processing window, PUF evaluations, and majority voting.

Therefore, the estimated latency is,

$$T_{auth} = 294 * 10ns = 2.94\ \mu s$$

The Vivado power analysis PUF+SNN estimates dynamic power consumption at 0.004W. SO the estimated energy per authentication is,

$$E_{auth} = 0.004 * 2.94 * 10\text{-}6 = 11.76nJ$$

The energy value is estimated from the Vivado power analysis and RTL-derived authentication latency.

VI. Conclusion and Future Work

The entropy is derived from three coupled components: the face biometrics, spiking neural nonlinearity, and the PUF. Their fusion is an effective security mechanism for improving ML and DL modeling resistance. It is suitable for resource-constrained IoMT devices due to its minimal FPGA usage. Compared to a conventional PUF-only or a biometric-only method, the proposed system transforms the biometric nonlinearly, making modeling attacks harder. There is no need for key storage, which offers resilience against spoofing and Man-in-the-Middle attacks. This facial biometric neuromorphic PUF security contributes towards the development of resilient and intelligent IoMT devices. Although the proposed work shows increased resistance against modeling attacks, the study has been evaluated on a single hardware platform and primarily for non-life-critical IoMT devices. Future investigations will consider multiple FPGA instances and environmental robustness. The future work will focus on extending the PUF to higher bit-widths for enhanced entropy, fusion of dynamic biometrics (ECG, iris) for different healthcare scenarios, and real-time deployment on wearable IoMT devices under practical operating conditions.

Availability of Data and Materials

The code and dataset used in the research are available at the GitHub link https://github.com/agilaharshini/Bio-SNN-PUF.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not- for-profit sectors.

Competing Interest

The authors (Dr. Harini S and Agilaharshini T) declare that there are no conflicts of interest related to this manuscript. No financial, professional, or personal relationships with organizations or individuals have influenced the research, analysis, or conclusions presented in this work.

Acknowledgment

The authors would like to take this opportunity to thank the management of Vellore Institute of Technology for providing the APC and encouragement to carry out this research.

***Abstract*—In Pakistan, wheat is one of the important crops, and the production of wheat is highly reliant upon the use of pure and certified seed varieties. Hence, wheat seeds should be properly identified to ensure the quality of the crop and better production. Farmers typically rely on a visual assessment of the varieties of seeds in practice. This technique is incorrect and prone to inaccuracies. Many seeds of wheat are very similar in shape and color. This wrong seed selection could lead to reduced yield and economic loss. To tackle this problem, this study proposes an automated machine learning based classification of wheat seed varieties. The experiments are carried out on six wheat varieties grown in Southern Punjab, Pakistan. This research utilizes the data obtained by taking digital images of wheat seeds under consistent lighting and a uniform background at three different resolutions: 256 x 256, 512 x 512, and 1024 x 1024. In seed analysis, texture is chosen to describe seed surface characteristics because texture information is best at differentiating visually similar seeds. These images are used to calculate the following features: Histogram Features, Texture Features, and Laws Texture Features using Spatial Gray Level Co-occurrence Matrices. These matrices are second-order statistics such as correlation, energy, contrast, and homogeneity calculated based on the relationship between the intensities of the pixels at various distances and orientations. Then, the derived features are optimized using Principal Component Analysis and Correlation Feature Selection. Five machine learning classifiers, namely LogitBoost (LB), BayesNet (BN), Classification Via Regression (CVR), Multi-Layer Perceptron (MLP), and Random Forest (RF), are employed. The classifiers are evaluated separately on the PCA-reduced and CFS-selected datasets for each image resolution. Classification accuracy and consistency were assessed. The experimental results indicated that the PCA optimized Dataset of 1024 x 1024 resolution and the Random Forest classifier gave excellent discrimination between the wheat varieties, and the classifiers achieved 96.4% accuracy for all the classes. The proposed system helps to minimize human judgment dependency and ultimately reduces the risk of misclassification at the early stage of cultivation. The method is non-destructive, economical. and applicable in agricultural applications.**

***Keywords*—Gray-Level Co-occurrence Matrix (GLCM); Principal Component Analysis (PCA); Correlation-based Feature Selection (CFS); Random Forest (RF); BayesNet (BN)**

I. INTRODUCTION

Wheat (Triticum aestivum L.) is an important cereal crop in the world and is a source of food for a large portion of the human population. Wheat is important in food production because of its versatility across different agro-climates, high nutritional content, and its broad use in foods, making it vital to global food security [1, 2]. In Pakistan, wheat is a major staple crop which plays a crucial role in rural livelihoods, agricultural productivity, and Pakistan's economic development. Wheat production has significantly improved due to the introduction of high-yielding wheat varieties, increased irrigation, use of fertilizers, and the use of modern cultivation methods since the Green Revolution, which has contributed to food security in the country [3]. However, the sustainability of wheat production is becoming a growing concern due to climate change, water scarcity, soil degradation, increasing temperatures, and increased occurrence of biotic stresses (such as pests and diseases) and abiotic stresses (such as drought, heat, and salinity) [4, 5].

In response to these difficulties, agricultural research stations have cultivated many wheat cultivars with greater yield capacity, disease resistance, drought resistance, and suitability to various environmental conditions [6]. As a result, a few wheat varieties have been grown throughout Pakistan, especially in the South of Punjab, where wheat farming is a critical part of the agricultural activities [7]. Careful choice of wheat cultivars is very important as they have different agronomic characteristics, growth requirements, stress tolerances, and yield potentials. Therefore, correct wheat variety identification and classification is crucial in agricultural production, varietal purity testing, wheat breeding, seed certification, and precision agriculture [8, 9].

The identification of varieties is traditionally done with the help of experienced wheat agronomists and seed analysts by manual inspection. These methods tend to be time-consuming, labour-intensive, subjective, and subject to human error, especially when differentiating morphologically similar cultivars [10, 11].

In recent years, there has been a growing demand for fast, accurate, and scalable classification approaches, which has encouraged the use of computer vision, digital image processing, and machine learning technologies in agricultural systems. These technologies can be used to automatically analyze the visual features of grains, including morphology, texture, color, shape, and structural characteristics. These features can help discriminate between different wheat varieties [12, 13].

Machine vision systems use vision equipment, sensors, and computational algorithms to accurately and consistently acquire and analyze visual information [14]. Machine vision systems can analyze a vast amount of data without getting tired or biased, which is very suitable for agricultural automation [11, 15]. This capability extends to image processing, where digital images are processed using image enhancement, image segmentation, feature extraction, and pattern recognition to transform the raw images into meaningful analytical information [13, 16]. The quantitative attributes derived from extracted features can be used by machine learning algorithms for classification and decision-making.

Over the past years, artificial intelligence has been used in crop classification in a way that has greatly enhanced its effectiveness. In recent years, machine learning models like Support Vector Machines (SVMs), ensemble classifiers, and deep learning models like Convolutional Neural Networks (CNNs) have achieved excellent performance in agricultural image analysis studies [8, 9]. These algorithms can be used to accurately classify wheat varieties and identify subtle differences in wheat morphology that may be difficult to visually distinguish from wheat images alone by learning discriminative patterns from wheat image sets [17, 18]. Therefore, image processing along with machine learning techniques has emerged as a viable approach for wheat classification where efficiency, accuracy, repeatability, and scalability are enhanced.

Although significant strides have been made in the field of agricultural machine vision, current research has mainly concentrated on the detection of diseases, monitoring of crop health, and binary classification, compared to the relatively limited work on the classification of wheat varieties in multiple classes with real-field image data sets and the development of sophisticated feature extraction techniques [19, 20]. Moreover, the establishment of advanced classification schemes that can differentiate the very similar wheat cultivars for a variety of conditions is an open research problem. Wheat is highly significant crop in Pakistan and as the demand for intelligent agricultural decision support systems is increasing, it is highly scientific and significant to develop an accurate and automated wheat classification framework.

Hence, this work aims to explore the use of machine learning and computer vision technologies for wheat variety classification. By integrating digital image processing, feature extraction, and advanced classification algorithms, the proposed framework aims to improve the accuracy and reliability of wheat classification. The approach is intended to support wheat variety identification and may have potential applications in seed certification and agricultural decision support.

II. Literature Review

With the advent of machine learning, computer vision, and deep learning, agricultural research has undergone a transformation, especially in the field of wheat seed and variety classification. Classification of wheat is essential to ensure varietal purity, crop management, seed certification, and better agricultural productivity. Practically, farmers' wheat seed identification methods are largely based on manual work and the expertise of experts. These methods are also time-consuming, subjective, and challenging to scale up. For this reason, automated image-based classification systems have been used. The classification is achieved by the use of digital image processing and machine learning algorithms to enhance its accuracy, efficiency and uniformity.[21, 22].

Initially researchers used handcrafted visual features of the wheat seed images such as color, shape, texture, area, perimeter, and geometric features. Wheat classification and seed quality assessment were often conducted with traditional machine learning algorithms like Support Vector Machines (SVM), Decision Trees, Random Forests, Naïve Bayes, and Artificial Neural Networks. The performance of these approaches was found to be encouraging, with classification accuracy frequently exceeding 90% [22-25]. SVM consistently performed better than other traditional classifiers in high-dimensional feature spaces and with limited training samples [21, 26, 27].

Wheat image analysis has also been largely influenced by texture-based feature extraction techniques. Gray-Level Co-occurrence Matrix (GLCM) descriptors and their related texture measures are broadly used to identify the discriminative visual patterns in wheat seed images and plant images. Several studies have demonstrated that texture features, in combination with machine learning classifiers, play a significant role in improving the classification result and also offer additional texture information beyond color and geometric measurements [28, 29]. Likewise, morphological and morphometric traits like kernel length, width, degree of kernel compactness, and groove dimensions are highly informative for wheat variety identification [26, 30].

Despite the limitations of handcrafted feature engineering, deep learning has emerged as a rapidly advancing field, thus moving research from manual feature engineering to automatic feature learning. In wheat classification, Convolutional Neural Networks (CNNs) are gaining popularity as the most prominent approach due to their capacity to extract complex visual features directly from raw images. Several CNN models are able to recognize tremendous classification accuracy on wheat seed datasets. A custom CNN architecture attained an accuracy of more than 97% for wheat classification [31], whereas transfer learning approaches with pretrained networks, including DenseNet201, MobileNet, and InceptionV3, revealed their effectiveness in improving classification performance [32]. More recent studies on Advanced CNN-based architectures have attained higher accuracy, exceeding 98% for wheat variety recognition [33-35].

Recently, there are also efforts on low-power deep learning algorithms for mobile devices and edge devices. Agricultural research is usually conducted in resource-limited environments, and decreasing the computational complexity without

compromising accuracy has become an important research goal. LWheatNet attained 98.59% classification accuracy with a model size of almost 1.33 MB [34]. Similarly, the G-PPW-VGG11 model for wheat field-based classification supports that lightweight networks can be used for real-time agricultural applications in achieving high accuracy. The studies indicate a shift towards more application-focused approach and smart farming [20].

Attention mechanisms and transformer-based architectures, which allow the model to focus on the most informative visual regions, have also improved the classification performance. Hybrid network models of CNN, attention modules, and recurrent networks have exhibited the best performance for learning delicate distinctions between wheat varieties having similar appearances. As an example, A hybrid Vision Transformer-CNN model attains an accuracy of 98.33% [36], and Xception-BiLSTM model achieves an accuracy of 97.73% [37]. Hard-voting groups also show good results with classification accuracy of up to 99% [33].

Hyperspectral imaging has also been identified as a potential non-destructive technique for wheat classification and for assessing wheat seed quality along with the RGB imaging. Hyperspectral sensors work differently from the standard imaging system. They are able to provide both spatial and spectral data, which are necessary for detailed characterization of wheat varieties. Multiple studies have combined hyperspectral imaging with machine learning algorithms, including SVM, Partial Least Squares Discriminant Analysis (PLS-DA), XGBoost, deep neural networks, and others, to deliver excellent classification accuracy [38-42]. The hyperspectral approaches show good performance, but they are costly to acquire and computationally intensive.

Another relevant research line is in the field of image segmentation and object detection techniques, which could be useful in enhancing the extraction of features, such as the isolation of wheat grains, spikes, and heads from the background. To meet the particular demands of agricultural production, several contemporary segmentation architectures have emerged to significantly enhance wheat object detection and wheat segmentation in real-world agriculture, including DeepLabV3+ [43], CBAM-HRNet [44], YOLOv8-HD [45]and semi-supervised encoder-decoder networks [46]. These advances enable more reliable feature extraction, resulting in improved classification performance.

In Pakistan, the study on the analysis of wheat using AI has significantly increased over the past few years. Local research has been done on wheat diseases, growth stage identification, yield prediction, and dataset development. A benchmark dataset with standardized images of major wheat varieties was presented, which is crucial for future machine learning research in Pakistan [47]. A hybrid MobileNetV2-DenseNet121 network was designed to obtain a recognition rate of about 99% for wheat growth stages [48]. Deep learning and image processing methods have been effectively used in wheat disease detection and yield prediction in the field and through remote sensing [49-51].

Although there are enormous advances in wheat classification studies, there are still some critical questions that have not been answered. Most of the previous studies have used publicly available international datasets or laboratory settings, which may not apply to local agricultural conditions [22, 25, 26]. Furthermore, Pakistani local wheat variety image datasets have been used in a limited number of studies [47]. Although deep learning, transformer-based, and ensemble methods have shown high classification accuracies, many of these approaches require considerable computational resources. This reduces their suitability for deployment on mobile devices and in resource-constrained agricultural environments [20, 33, 36]. Additionally, the focus of most of the existing studies is only on classification performance, and little attention is paid to the translation of classification results into practical recommendations for agronomic operations that can be used directly by farmers in their decision-making processes.

Hence, robust and efficient machine learning models are required to achieve precise Pakistani wheat variety classification using image-based data. Such systems should also support practical agricultural decision-making by linking variety classifications with crop management. These can contribute to precision agriculture and sustainable wheat production.

III. METHODOLOGY

A. Proposed Methodology

The main goal of the study is to propose an automated method of identifying wheat seed varieties based on digital image data. The proposed framework is depicted in Figure 1 that describes the entire process of classifying wheat seed varieties. These six steps represent the entire process.

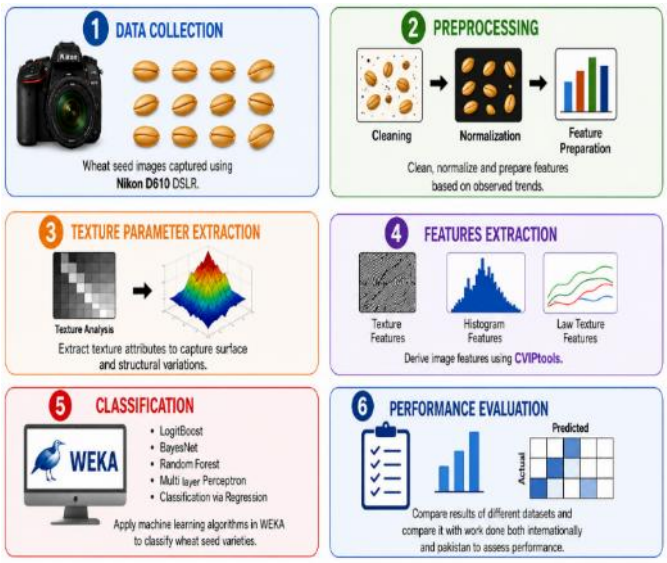

Fig. 1. Proposed methodology framework.

B. Study Area and Wheat Varieties

A total of six wheat varieties were used in the study, which are commonly grown in Southern Punjab, Pakistan, namely Akbar-19, Dilkash-20, Inqalab-91, Sadiq-21, Nawab-21 and Ghazi-19. Wheat seed samples were gathered from Bahawalpur, Multan, and Dera Ghazi Khan districts. These varieties were carefully chosen because of their agricultural importance and widespread cultivation in these areas.

C. Image Acquisition

Wheat seeds images were captured by using a Nikon D610 DSLR camera equipped with a 24-megapixel sensor under controlled studio lighting. Each of the 300 images was a single physical sample of seed, and 50 samples were taken from each of the six varieties: 50 x 6 = 300 images. So, no repeated images of the same physical seed were present throughout the dataset. Environmental variability was minimized by maintaining a fixed camera setup, a uniform background, and consistent lighting throughout the image acquisition process. Sample images of each variety used in this research are shown in Figure 2.

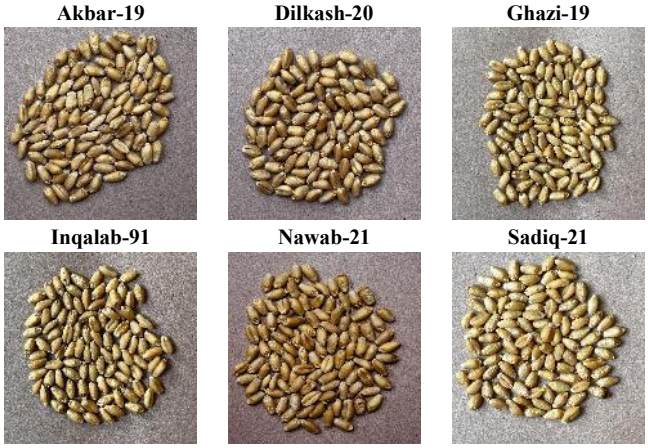

Fig. 2. Wheat seed images.

D. Image Preprocessing

The captured images were resized to three different resolutions: 256×256, 512×512, and 1024×1024 pixels to explore the effect of image scale on classification accuracy. RGB images were converted into grayscale images to simplify the computation required while maintaining structural and texture information. Image enhancement and normalization techniques were applied to improve contrast and reduce noise. Preprocessing enhanced image quality and normalized the dataset for analysis. Given an image $I(x, y)$, normalization is computed as:

$$I_n(x, y) = \frac{I(x,y)-\mu}{\sigma} \quad (1)$$

where μ is the mean intensity and σ denotes the standard deviation. This step helps to minimize illumination variations and improve relevant features. Noise reduction techniques were also applied to improve image clarity.

E. Feature Extraction

CVIPtools software was used for feature extraction. Three types of descriptors were extracted: histogram features, Gray-Level Co-occurrence Matrix (GLCM) texture features, and Laws texture features. Five regions of interest (ROIs) on individual seeds were selected randomly from each image to capture local texture variations, as tabulated below. Based on ROI circle size in Table 1, nine datasets comprising 91 features(Histogram, Texture, and Laws Texture) were extracted.

TABLE I. SUMMARY OF ROI USED FOR EACH DATASET

Sr. No	Datasets	ROI Circle Radius Size
	256 x 256	12 Pixels 14 Pixels 16 Pixels
	512 x 512	14 Pixels 16 Pixels 18 Pixels
	1024 x 1024	16 Pixels 18 Pixels 20 Pixels

F. Histogram Features

Histogram analysis represents the intensity distribution of image pixels [52]:

$$p(i) = \frac{n_i}{N} \quad (2)$$

where $\boldsymbol{n_i}$is the number of pixels with intensity $\boldsymbol{i}$and $\boldsymbol{N}$is the total number of pixels**.**

Mean:

$$\mu = \sum_{i=0}^{L-1} i \cdot p(i) \quad (3)$$

Variance**:**

$$\sigma^2 = \sum_{i=0}^{L-1} (i-\mu)^2 p(i) \quad (4)$$

Entropy**:**

$$H = -\sum_{i=0}^{L-1} p(i) \log p(i) \quad (5)$$

G. Gray-Level Co-occurrence Matrix (GLCM) Features

GLCM was employed to quantify spatial relationships between neighboring pixels. Texture features were computed in four orientations (0°, 45°, 90°, and 135°). The principal Haralick descriptors used in this study include Contrast, Correlation, Homogeneity, Energy (Angular Second Moment), and Entropy [53].

$$P(i,j) = \frac{\text{Frequency of pixel pair } (i,j)}{\text{Total number of pairs}} \quad (6)$$

Derived features include:

Contrast:

$$\text{Contrast} = \sum_{i,j} (i-j)^2 P(i,j) \quad (7)$$

Energy:

$$\text{Energy} = \sum_{i,j} P(i,j)^2 \quad (8)$$

Correlation:

$$\text{Correlation} = \frac{\sum_{i,j}(i-\mu_i)(j-\mu_j)P(i,j)}{\sigma_i \sigma_j} \quad (9)$$

Homogeneity:

$$\text{Homogeneity} = \sum_{i,j} \frac{P(i,j)}{1+|i-j|} \quad (10)$$

These measures capture structural and spatial properties of wheat seed textures.

H. Laws Texture Features

Laws texture energy measures were extracted using convolution masks derived from the one-dimensional kernels L5, E5, S5, W5, and R5. These filters capture texture patterns associated with level, edge, spot, wave, and ripple structures. Symmetric masks were combined to reduce feature redundancy and improve computational efficiency.

- L, E, S, W, R represent:
  - L (Level): Average or smooth intensity in the image.
  - E (Edge): Edge detection (intensity changes) for texture.
  - S (Spot): Identifies spot-like patterns in the image.
  - W (Wave): Captures wave or oscillatory patterns.
  - R (Ripple): Identifies fine ripple or repetitive texture.

Law's texture energy measures use convolution masks to extract local texture information (Laws, 1980). The masks are formed using 1D vectors such as:

Level (L5): $[1\ 4\ 6\ 4\ 1]$

Edge (E5): $[-1\ -2\ 0\ 2\ 1]$

Spot (S5): $[-1\ 0\ 2\ 0\ -1]$

The 2D mask is generated as:

$$\text{Mask} = V_i^T \cdot V_j \tag{11}$$

Texture energy is computed as:

$$E = \frac{1}{MN} \sum_{x,y} | I(x,y) * \text{Mask} | \tag{12}$$

where $*$denotes convolution.

I. Feature Optimization

Principal Component Analysis (PCA) and Correlation-based Feature Selection (CFS) were used separately to reduce the dimensionality and remove redundant information from the extracted feature sets. PCA was used to reduce the size of the feature space while retaining the major variance in the data, whereas CFS was used to select attributes with high relevance and low inter-correlation. For each image resolution, PCA and CFS were applied separately to the complete extracted feature dataset, and separate data files were generated for the PCA-optimized and CFS-optimized feature sets. The resulting datasets contained 25 PCA features and 21 CFS-selected features, respectively. These optimized datasets were subsequently used for classification with the selected machine learning algorithms in WEKA. The classification performance was evaluated using 10-fold cross-validation. Thus, PCA and CFS were performed before the cross-validation stage and were not independently fitted within each training fold.

In general, the extracted feature vector is:

$$X_{opt} = [f_1, f_2, \dots, f_m] \tag{13}$$

where:

X_{opt}= optimized feature vector after feature reduction.

$f_1, f_2, \dots, f_m$= selected features.

m= number of retained features after optimization.

J. Classification Models

Five supervised machine learning algorithms implemented in WEKA 3.8.2 were evaluated: LogitBoost, BayesNet, Classification via Regression, Multi-Layer Perceptron (MLP), and Random Forest using default settings. In order to ensure uniformity, the same configurations were applied to all feature-optimized datasets for performance comparison. The classification performance was evaluated using 10-fold cross-validation. The selected algorithms have been used in agricultural classification tasks. These models learn a mapping function:

$$f: \mathrm{X} \rightarrow Y \tag{14}$$

where Y denotes the class label of wheat seed varieties.

K. Performance Evaluation

The 10-fold cross-validation was performed on the PCA-optimized and CFS-optimized datasets after the respective feature-selection procedures had been completed. The classification performance was measured by the following performance metrics: Accuracy, Precision, Recall, and F1-score. The classifiers were compared based on these performance measures to determine the most effective classifier. The classification results were also compared with recent studies from Pakistan and other countries that have been reported in the literature. The evaluation of the performance of the models is performed with classification measures:

Accuracy:

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \tag{15}$$

Precision:

$$\text{Precision} = \frac{TP}{TP+FP} \tag{16}$$

Recall:

$$\text{Recall} = \frac{TP}{TP+FN} \tag{17}$$

F1-Score:

$$F1 = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \tag{18}$$

A confusion matrix is used to visualize classification performance. Comparative evaluation is carried out among classifiers and benchmarked with existing national and international studies.

IV. Results

Six Pakistani wheat varieties were considered: Akbar-19, Dilkash-20, Ghazi-19, Inqalab-91, Nawab-21 and Sadiq-21. Digital images of these varieties were taken and used to evaluate the proposed wheat seed classification system. The experiments were carried out using three image resolutions (256×256, 512×512, and 1024×1024 pixels) to explore the effect of image quality on classification performance. GLCM having Texture features, Histogram features, and LBP texture features were obtained for each ROI in wheat seed regions.

Principal Component Analysis (PCA) and Correlation-based Feature Selection (CFS) were used for dimensionality reduction and feature selection, respectively. PCA was performed in WEKA using a cumulative variance retention threshold of 95% (-R 0.95), resulting in 25 principal components. CFS was performed using CfsSubsetEval with BestFirst search in the forward direction and default search parameters, resulting in 21 selected features. CfsSubsetEval evaluates feature subsets by considering the correlation between the selected features and the class while reducing redundancy among the selected features. The resulting PCA and CFS feature sets were used separately for classification at each image resolution.

The optimized feature sets were then classified using different machine learning algorithms. Previous research in this field has also reported that image-based feature extraction and machine learning provide an effective approach for automated wheat variety identification [24, 54].

The classification accuracy varied with the dimensionality reduction and feature selection methods. The major variance patterns were preserved, and important discriminative texture information was retained by PCA, giving better results than CFS. While CFS reduced the number of features, some information related to the seed surface characteristics was lost. The results showed that there are some subtle differences in the texture of the different wheat varieties and that the ability to preserve these differences is essential for the correct classification.

The performance of the machine learning classifiers varied with the selected features and image resolution in the 10-fold cross-validation experiments. Higher-resolution images generally delivered higher classification accuracy. This may be because they kept more detailed information about seed texture, shape, and surface patterns.

A. Classification Performance Analysis Using PCA Optimized Features

Table 2 presents classification performance of five machine learning classifiers using PCA-optimized features extracted from wheat seed images at three different resolutions (256×256, 512×512, 1024×1024).

TABLE II. ACCURACY COMPARISON OF CLASSIFIERS (PCA OPTIMIZED)

Classifier	Accuracy (%) Dataset 256 x 256	Accuracy (%) Dataset 512 x 512	Accuracy (%) Dataset 1024 x 1024
LogitBoost	86.00	91.73	92.40
BayesNet	84.07	92.13	88.80
ClassificatoinViaRegression	88.53	92.67	94.20
MultilayerPerceptron	87.60	91.53	93.80
RandomForest	92.80	94.67	96.40

The performance of five classification machine learning algorithms is presented for the three different resolution images of wheat seeds extracted from the images using PCA in Table 2. The corresponding classification accuracies are shown in Figure 3. The results reveal that the image resolution has a positive effect on the classification accuracy since the higher the image resolution, the more discriminative texture and structural information of the wheat seed variety could be obtained. The results also reveal that feature representation and the selection of the corresponding learning algorithm are crucial for classification accuracy.

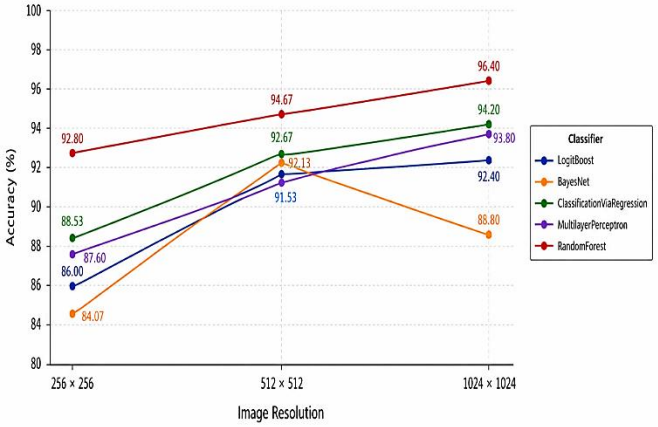

Fig. 3. Classification accuracy of different classifiers (PCA optimized).

Random Forest amongst all classifiers, has shown the highest accuracy for all image resolutions, with accuracies of 92.80%, 94.67%, and 96.40% for 256×256, 512×512, and 1024×1024 datasets, respectively. Random Forest outperforms other methods because it follows the ensemble learning method, with multiple decision trees working together to enhance the accuracy of classification and minimize errors.

The performance of ClassificationViaRegression was also found to steadily improve with increasing resolution of the images, with the results of 88.53%, 92.67%, and 94.20%, respectively. Likewise, LogitBoost and MultilayerPerceptron showed higher accuracy with higher-resolution images, suggesting that the higher-resolution images provided better feature representation. BayesNet performed well at 512×512 resolution but showed lower accuracy at 1024×1024 resolution, indicating a possible limitation in the ability of the model to capture higher dimensional relationships between the image feature dimensions.

The overall results indicate that PCA preserved important discriminative features in the wheat seed images. The combination of PCA and Random Forest achieved the best classification performance, and it is observed that it achieves the highest accuracy in the highest resolution data (96.40%). The results presented here emphasize the necessity of using image quality, feature optimization, and classifier selection in developing reliable wheat seed classification systems.

B. Classification Performance Analysis Using CFS Optimized Features

Table 3 shows the classification performance of five machine learning classifiers, trained with features optimized by CFS on the wheat seed images with three different image resolutions: 256×256, 512×512, and 1024×1024 pixels.

The results shown in Table 3 indicate that both the selected feature subset and the learning algorithm had influenced the classifier performance. CFS-based feature selection resulted in

lower classification accuracy as compared to PCA optimization. Figure 4 shows a graphical representation of their classification accuracy results. This indicates that some important discriminative information essentials for wheat variety classification was lost during feature reduction.

TABLE III. ACCURACY COMPARISON OF CLASSIFIERS (CFS OPTIMIZED)

Classifier	Accuracy (%) Dataset 256 x 256	Accuracy (%) Dataset 512 x 512	Accuracy (%) Dataset 1024 x 1024
LogitBoost	70.53	73.87	71.53
BayesNet	67.67	67.53	68.80
ClassificatoinViaRegression	79.07	77.33	**75.80**
MultilayerPerceptron	65.47	68.93	73.60
RandomForest	**85.27**	**84.33**	75.47

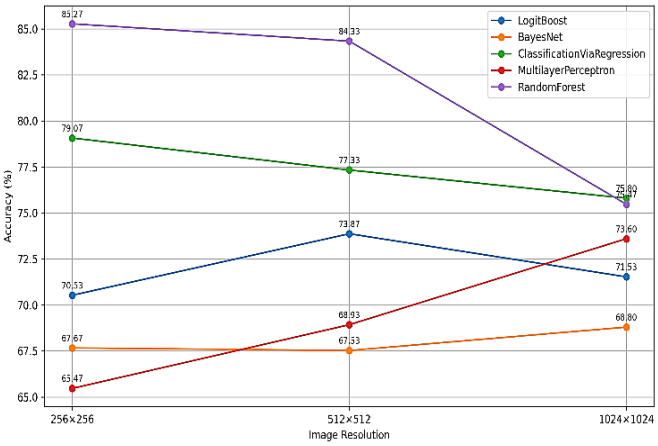

Fig. 4. Classification accuracy of different classifiers (CFS optimized).

In comparison, LogitBoost performed relatively stably on the image resolutions with an accuracy of 70.53%, 73.87% and 71.53% for 256×256, 512×512 and 1024×1024, respectively. In addition, BayesNet delivered similar results with a range of 67.53%-68.80%, indicating some consistency but not as effective as the other classifier in modelling complex relationships among the selected seed features.

ClassificationViaRegression achieved accuracies of 79.07%, 77.33%, and 75.80% for all the three datasets. However, its accuracy decreased slightly with increasing image resolution. This suggests that the CFS-selected features did not fully keep the additional information available in higher-resolution images. In contrast, MultilayerPerceptron showed gradual improvement from 65.47% to 73.60%, indicating better utilization of additional feature information at higher resolutions.

Random Forest achieved the highest accuracy for the 256×256 and 512×512 datasets, with accuracies of 85.27% and 84.33%, respectively. However, its performance decreased to 75.47% for the 1024×1024 dataset. This reduction suggests that the CFS-selected feature subset was less effective in representing complex patterns from higher-resolution images. Overall, the results confirm that although CFS reduced the feature dimensionality, PCA optimization retained more informative features and provided superior classification performance for wheat seed variety classification.

C. Performance Comparison of Both PCA and CFS Optimized Features

Table 4 and Table 5 report the performance of the proposed model and baseline methods with various evaluation measures. These metrics provide complementary information for overall classification accuracy, class-wise prediction performance, and discriminative ability. This allows a more comprehensive comparison of model effectiveness.

TABLE IV. ACCURACY COMPARISON OF CLASSIFIERS (PCA OPTIMIZED)

RandomForest	512×512	0.812	0.843	**0.977**
RandomForest	**1**024×1024	0.7056	0.753	0.949

The Random Forest classification rate was 96.4% but was also supplemented with other evaluation parameters such as Precision, Recall, F1-Score, Specificity and AUC-ROC presented in Tables 4 and 5. These metrics provide alternative information about the accuracy of the classifier in correctly predicting positive and negative cases while considering false-positive and false-negative rates and in properly separating classes. The overall high values for all these metrics justify the classification rate reported as 96.4% for the Random Forest classifier and give evidence of good and reliable classification.

D. Comparison with International Research

The results obtained were compared with previous international wheat classification studies. Kayabaşı et al. [54] achieved approximately 93% accuracy using texture and morphological features with artificial neural networks. Basati et al. [24] reported around 90.20% accuracy using color, morphology, and texture features with decision tree classification. Singh et al. [55] reported 97.70% accuracy using advanced feature representation and fuzzy clustered random forest. Lüy et al. [28] achieved 82.20% accuracy by using GLCM texture features and grain characteristics as mentioned in Table 6.

TABLE VI. COMPARISON WITH INTERNATIONAL STUDIES ON WHEAT SEED CLASSIFICATION USING TEXTURE/IMAGE FEATURES AND MACHINE LEARNING

Study	Features Used	Classifier	Accuracy (%)	Comparison with Present Study
Kayabaşı et al. (2017)	Image texture and morphological features	ANN	93.00	Present study achieved higher accuracy (96.40%) using PCA and RandomForest
Basati et al. (2018)	Color, morphology, and texture features	Decision Tree (J48)	90.20	The present study improved classification accuracy by more than 6%.
Singh et al. (2020)	Visual grain characteristics	Fuzzy Clustered Random Forest	97.70	Slightly higher than the present study; however, it focused on grain grading rather than classification of multiple wheat varieties.
Lüy et al. (2023)	GLCM texture features and grain characteristics	Machine Learning	82.00	The present study substantially outperformed the reported results that time.
Present Study	GLCM texture and intensity features + PCA	RandomForest	**96.40**	The present study achieved 96.40% accuracy among reviewed texture-based varietal classification studies.

Studies are noted in Table 6, with the difference among them in respect to the number of wheat classes, the number of datasets, the setup of acquiring images, image preprocessing, and the way the studies are validated. All of this can have significant impact on classification accuracy and on the validity of direct one-on-one comparisons. The reported accuracies are therefore listed, in particular, to provide a benchmark in this research. Compared with these studies, the proposed PCA-based Random Forest framework achieved competitive performance while using a comparatively simple and computationally efficient machine learning approach.

E. Comparison with Pakistani Research Studies

The proposed method was also compared with recent studies conducted in Pakistan, as shown in Table 7.

TABLE VII. COMPARISON WITH RESEARCH CONDUCTED IN PAKISTAN

Study	Research Focus	Method	Accuracy (%)	Comparison with Present Study
Nawaz et al. (2025)	Development of Pakistani wheat seed dataset	Dataset Creation	N/A	Provides a dataset but not a classification framework.
Yasar et al. (2024)	Bread wheat variety classification	CNN + SVM	94.00	GLCM features were not used.
Yasar et al. (2024)	Bread wheat variety classification	ResNet18s	97.57	GLCM features were not used.
Usman et al. (2024)	Wheat seed disease classification	CNN	98.43	Different tasks focusing on disease detection rather than variety classification. Further, CNN-based methods are more accurate, but they normally require more data, GPU resources, and long training time. A quantitative comparison of computational resources was not performed in the present study.
Ashraf et al. (2023)	Wheat disease recognition	CNN	93.00	Different application domain.
Present Study	Six Pakistani wheat varieties	PCA + RandomForest	96.40	One of the highest accuracies reported using traditional machine-learning techniques.

The performance of the proposed wheat seed classification framework was compared with recent studies conducted in Pakistan, as summarized in Table 7. Existing studies have mainly focused on wheat variety classification using deep learning approaches or wheat disease recognition, whereas the present study focuses on automatic classification of six Pakistani wheat varieties using texture-based features and traditional machine learning. Further, the accuracy reported is a contextual benchmark for wheat seed classification research in Pakistan. But caution should be taken in making direct one-to-one comparisons due to the differences in the size of the data sets, wheat varieties, the way the images were taken, the preprocessing methods, and how the images were validated. These factors may influence the accuracy in the classification and can have an impact on the comparability of accuracy values reported.

Nawaz et al. [47] developed a Pakistani wheat seed image dataset, which provides an important resource for future research; however, the study did not present a complete classification framework. Yasar et al. [56] achieved 94.00% and 97.57% accuracy using CNN-SVM and ResNet18 models, respectively, for bread wheat variety classification. However, these approaches relied on deep learning architectures and did not utilize GLCM-based handcrafted texture features. Similarly, Usman et al. [51] and Ashraf et al. [49] reported high accuracies using CNN models, but their studies focused on wheat disease detection rather than variety identification.

In comparison, the proposed PCA-optimized Random Forest framework attains an accuracy of 96.40% for six Pakistani wheat varieties. The results show that the proposed approach presents competitive performance with deep learning-based approaches, requiring comparatively lower computational complexity using handcrafted features and a Random Forest classifier. A quantitative comparison of computational complexity with deep learning approaches was not performed in this study. The results highlight the potential of optimized texture features along with machine learning algorithms for wheat seed variety classification.

F. Research Contributions

This work provides a framework for wheat seed variety classification using image acquisition, image preprocessing, texture and intensity-based feature extraction, feature dimensionality reduction and selection, and machine learning. The framework can support research in agricultural image analysis and wheat seed classification. The framework proposed is applicable to small and medium-sized datasets in the agricultural context and can be adapted to other classification problems of crops. The comparison of five classifiers (LogitBoost, BayesNet, ClassificationViaRegression, MultilayerPerceptron, and RandomForest) shows that the choice of a particular classifier, as well as feature optimization, has a pronounced effect on the quality of the classification result. The wheat variety identification results demonstrated that the PCA-optimized RandomForest model gave the highest accuracy of 96.40%; thus, it is effective in wheat variety identification tasks. This study offers fresh empirical data on the texture features of wheat varieties grown in South Punjab, Pakistan, and fills the gap of wheat seed image datasets and classification studies in the region. The proposed method shows that the handcrafted texture features and the traditional machine learning algorithms can accurately distinguish wheat seed varieties without being destructive, quickly, and cheaply. The proposed framework has potential applications in seed identification, varietal verification, and agricultural image analysis. It may also provide a basis for future research involving deep learning, hybrid feature extraction, and larger agricultural datasets.

V. CONCLUSION

In this study, a complete image-based wheat variety classification framework based on machine learning techniques was presented. Whereas the previous work was performed on benchmark datasets like the UCI Wheat Seeds dataset, this study is based on a real-world image dataset of six wheat varieties from Pakistan, namely Akbar-19, Dilkash-20, Ghazi-19, Inqalab-91, Nawab-21, and Sadiq-21. The use of locally cultivated wheat varieties with similar visual characteristics makes the classification problem more difficult and practically relevant. The study provides a detailed image-based classification framework for Pakistani wheat varieties. It also addresses the limited availability of local wheat seed image datasets.

Five machine learning classifiers, including LogitBoost, BayesNet, ClassificationViaRegression, MultilayerPerceptron, and RandomForest, were systematically compared in their performance, with identical experimental conditions. The results showed that the choice of classifiers has a remarkable impact on the classification accuracy, with the highest accuracy of 96.40% achieved by PCA-optimized features with RandomForest. This study also examined the influence of the image resolution, by comparing the performance of image datasets with resolutions of 256×256, 512×512 and 1024×1024, with higher resolution images generally yielding better classification results as more discriminative texture and intensity information was available.

One of the key findings of this research is that handcrafted features used for texture and intensity are employed instead of deep learning-based features extraction. The results show that traditional machine learning methods can achieve high classification accuracy using handcrafted texture and intensity features. The present study did not quantitatively evaluate computational requirements or compare them with deep learning models. Therefore, computational efficiency should be investigated separately in future work. In addition, the comparison of PCA and CFS feature optimization methods demonstrated that PCA preserved more informative features and that it gave better classification results when identifying wheat seeds.

VI. LIMITATIONS

Overall, the proposed framework was able to provide good classification performance, but there are some limitations that should be considered. The dataset used includes six varieties of wheat from Pakistan and was sampled under controlled imaging conditions; thus, the model needs to be tested with more varieties, different regions, and different environmental conditions. Second, the image acquisition process was conducted under relatively controlled imaging conditions, which may induce some variations in illumination, background

noise, seed orientation, and image quality in an actual agricultural environment that can impact the classification performance. Third, the study is primarily based on handcrafted texture and intensity features, which can achieve good classification results, but the performance of the proposed handcrafted-feature approach was not directly compared with deep learning-based feature extraction in this study. In addition, the data size is relatively small, especially when compared to the large-scale deep learning applications. Future work needs to be directed towards building larger and more diverse wheat seed image datasets and testing the hybrid or deep learning approach to gain robustness and scalability.

VII. Future Work

The proposed framework provides a trustworthy, inexpensive, and efficient solution for wheat variety classification. This performance achieved shows its possible use in seed certification, verification of variety, grain quality, and smart systems in agriculture. The dataset developed, methodology, class performance evaluation, and experimental results will serve as a benchmark for future research on deep learning-based frameworks, hybrid feature extractors, seed quality analysis, and large-scale agricultural automation in the context of agriculture in Pakistan and other developing countries.

Acknowledgment

The authors would like to express their sincere gratitude to the Department of Information Technology, The Islamia University of Bahawalpur, for providing the facilities and support required to complete this research. The authors also thank all individuals who assisted in the collection and preparation of the wheat seed dataset. Their support and valuable contributions are greatly appreciated.

Perceptual Evaluation of Garment Drape Intensity in AI-Generated Garment Images

A Pilot Study Using a Semi-Automated Evaluation Pipeline with CLIP

***Abstract*—Recent advances in generative artificial intelligence have enabled fine-grained manipulation of visual attributes in garment images, but consistency in automated feature space does not necessarily guarantee consistency in human perception. This study investigates the perceptual validity of garment drape intensity control in AI-generated garment images using a semi-automated Human-in-the-Loop evaluation pipeline. Five base garments were manipulated across five latent-space control levels and evaluated independently using Contrastive Language–Image Pre-training (CLIP)-based feature-space analysis and a two-alternative forced-choice (2AFC) experiment with 15 participants. The CLIP projection scores increased monotonically with the manipulation parameter for all five garment sequences. Human judgments showed a similar monotonic tendency at the aggregate level; however, garment-specific Bradley–Terry analysis revealed local reversals in the estimated perceptual ordering for three of the five base garments. These results demonstrate that aggregate agreement between automated and human evaluation can mask stimulus-specific perceptual discrepancies. The proposed framework provides a practical approach for combining automated screening with human perceptual validation when assessing fine-grained attributes in generative fashion systems.**

***Keywords*—Drape perception; generative AI; human-in-the-loop; CLIP; bradley–terry model; fashion image generation**

I. Introduction

Generative models have increasingly enabled fine-grained control of visual attributes in synthesized images. Diffusion-based and latent diffusion models have provided a flexible foundation for high-quality and controllable image generation [1], [2]. In the fashion domain, generative models are being applied to garment generation, editing, virtual try-on, and design support [3]. Beyond generating visually plausible garments, an important challenge is to determine whether controlled changes introduced by generative models correspond to visual differences that are consistently perceived by human observers.

This issue is particularly relevant for perceptual garment attributes. A generative model may produce systematic changes in its latent representation or in an automated feature space, but such changes do not necessarily imply equally systematic changes in human perception. Recent work on human-preference-based evaluation of generated images has also highlighted the importance of evaluating correspondence between automated representations and human judgments [4]. Drape provides a useful case for examining this problem because its visual impression emerges from multiple garment-dependent characteristics, including folds, silhouette, and the apparent manner in which fabric hangs. The perceived strength of drape may therefore depend not only on the magnitude of the generative manipulation but also on the visual context of the individual garment.

Our previous study proposed an evaluation framework combining latent-space analysis, CLIP-based automated evaluation, and human perceptual judgments to assess the reliability of attribute control in diffusion-based fashion generation [5]. The present study extends this approach to garment drape as a textile-oriented perceptual attribute. Latent-space manipulation is employed because it enables systematic variation of a target attribute along a continuous control parameter while using the same base garment as a reference. This controlled setting is particularly useful for perceptual evaluation, where changes in the target attribute should be distinguished from unrelated variations in garment appearance. Rather than examining only whether an automated score changes monotonically with the manipulation parameter, we investigate whether the corresponding perceptual ordering is reproduced by human observers and whether this correspondence remains consistent across individual base garments. In this study, the term drape intensity is used operationally to denote the perceived strength of drape in AI-generated garment images and is not intended to represent a conventional physical property of textiles.

To address these questions, we employ a semi-automated Human-in-the-Loop evaluation pipeline integrating latent-space quality control, CLIP-based feature-space evaluation, and a two-alternative forced-choice (2AFC) perceptual experiment analyzed using the Bradley–Terry model. The main contributions of this study are threefold: 1) we operationalize drape intensity as a perceptual attribute for controlled evaluation of AI-generated garment images; 2) we apply and extend our previously proposed semi-automated evaluation framework to garment drape, with automated feature-space behavior and human perceptual judgments evaluated independently and subsequently compared; and 3) we demonstrate that aggregate agreement between automated and human evaluation can mask garment-specific perceptual discrepancies. Through this analysis, the study examines the role of human perceptual validation in assessing fine-grained attribute control in generative fashion systems.

II. Related Work

A. Textile Drape Measurement and Perceptual Evaluation

Drape has long been studied in textile and apparel engineering as a property arising from the interaction between fabric mechanical characteristics, gravity, and garment construction. Early quantitative approaches introduced drape coefficients and related geometric measures to characterize the deformation of fabric under its own weight [6]. Subsequent work extended such physical evaluation by examining static and dynamic drape behavior and its relationship to fabric characteristics [7].

In parallel with physical measurement, subjective and visual evaluations have been used to investigate how drape is perceived as part of garment appearance. Studies have examined the aesthetic impression of drape [8], the effects of material properties on gathered skirts and their visual evaluation [9], and the formation and visual characteristics of drape in flared-skirt models [10, 11]. Other studies have related the silhouettes of flared and gathered skirts to fabric mechanical, bending, and vibration properties [12, 13]. Together, these studies demonstrate that garment drape is not solely a physical material property but also a perceptual phenomenon influenced by garment structure and visual appearance.

The present study differs from this conventional line of textile research in that no physical fabric is measured. Instead, we examine the perceived drape of synthetically manipulated garment images generated by a diffusion model. Accordingly, drape intensity is used here as an operational perceptual term rather than as a substitute for conventional physical measures such as the drape coefficient. This distinction allows established knowledge of garment drape perception to be connected with the emerging problem of perceptual validation in generative fashion imagery.

B. Generative AI and Attribute Control in Fashion

Recent progress in image generation has shifted attention from the synthesis of realistic images toward controllable generation and editing. Diffusion models provide a flexible foundation for this transition by progressively reconstructing images from noisy representations [1]. Latent diffusion further reduces the computational burden of this process by performing generation in a compressed representation space, enabling practical high-resolution synthesis and editing [2]. Additional conditioning mechanisms have subsequently been introduced to provide more explicit control over generated content. For example, ControlNet incorporates structural conditions into diffusion-based generation [14], while instruction-guided approaches enable existing images to be modified according to natural-language descriptions [15].

Another line of research has investigated whether interpretable visual changes can be produced by manipulating internal representations of generative models. Studies based on GANs demonstrated that variations in attributes can be associated with directions or subspaces within learned latent representations. InterFaceGAN identified semantic boundaries that support controlled manipulation of facial attributes [16], whereas GANSpace derived interpretable controls from principal directions in intermediate latent representations [17]. StyleCLIP further demonstrated that language-based semantic information can be connected to latent editing operations [18]. Although these approaches differ in architecture and manipulation strategy, they collectively show that learned representations can support continuous and interpretable changes in generated images.

Such controllability is particularly relevant to fashion, where the usefulness of generative systems depends not only on image realism but also on the ability to preserve garment identity while modifying selected characteristics. Recent reviews describe applications of generative AI to fashion design, garment synthesis, virtual try-on, and image editing, while also identifying fine-grained controllability and evaluation as continuing challenges [3]. However, successful manipulation in a generative representation does not by itself establish that the intended attribute change is visually interpreted in the same way by human observers. For perceptual garment attributes such as drape, this distinction motivates an evaluation framework that considers not only the behavior of the generative representation but also the resulting human perceptual response.

C. Automated Evaluation and Human Perceptual Alignment

The increasing capability of generative models has created a corresponding need for scalable methods to evaluate generated images. Vision-language models provide one approach by representing visual and linguistic information within related feature spaces. CLIP, trained through contrastive learning on large-scale image–text pairs, has become a widely used representation for measuring semantic relationships between images and textual concepts [19]. Other approaches have moved beyond general image–text similarity toward models trained to approximate human preferences for generated images. Examples include ImageReward [20] and Human Preference Score v2 [4], which use human preference data to improve the correspondence between automated evaluation and subjective judgments.

The existence of such preference-oriented metrics also reflects an important limitation of purely automated evaluation: a systematic change in a learned representation is not necessarily equivalent to a systematic change in human perception. Deep perceptual metrics such as LPIPS have demonstrated that learned visual representations can capture aspects of perceptual similarity more effectively than simple pixel-level measures [21]. Nevertheless, perceptual judgments remain dependent on the task, the visual attribute under consideration, and the context in which that attribute appears. Consequently, automated metrics are useful for characterizing generated-image behavior but cannot automatically be treated as substitutes for task-specific human validation.

Human paired-comparison methods provide a complementary means of evaluating subtle perceptual differences without requiring participants to assign absolute numerical values to visual attributes. In a two-alternative forced-choice (2AFC) experiment, observers select one of two stimuli according to a specified perceptual criterion, allowing comparative judgments to be collected under a relatively simple task design [22]. Models for paired-comparison data, such as the Bradley–Terry model, can then transform these outcomes into latent worth estimates representing relative perceptual strength

[23]. This combination is particularly useful when the experimental question concerns the ordering of a continuously manipulated attribute rather than the assignment of an absolute physical quantity.

In our previous work, we combined latent-space diagnostics, CLIP-based evaluation, and human paired-comparison judgments to investigate perceptual reliability across multiple controlled attributes in diffusion-based fashion generation [5]. That study showed that agreement among the different evaluation layers varied across attributes, motivating closer examination of cases in which automated and perceptual assessments do not coincide. The present study takes a more focused approach by treating garment drape as a textile-oriented perceptual attribute and by examining correspondence at the level of individual base garments. This shift from multi-attribute aggregate validation to garment-specific analysis enables us to investigate whether apparently consistent automated trajectories can conceal stimulus-dependent differences in human perceptual ordering.

III. METHOD

A. Overview of the Semi-Automated Evaluation Pipeline

To evaluate whether latent-space attribute manipulation produces perceptually meaningful changes in garment drape, we developed a semi-automated evaluation pipeline that integrates AI-based stimulus generation, human perceptual evaluation, and automated feature-space evaluation into a unified experimental workflow. Rather than relying solely on either human judgment or automated metrics, the proposed pipeline enables systematic comparison between the two evaluation tracks, thereby providing a reproducible framework for assessing the perceptual validity of latent attribute manipulation.

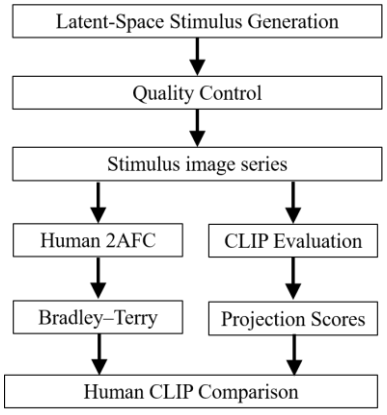

Fig. 1. Overview of the semi-automated evaluation pipeline. Human perceptual evaluation and CLIP-based feature-space evaluation are conducted as parallel tracks and subsequently compared to assess perceptual consistency.

As illustrated in Fig. 1, the pipeline consists of five functional stages: 1) stimulus generation by latent-space manipulation, 2) quality control of generated stimuli, 3) human perceptual evaluation using a web-based two-alternative forced-choice (2AFC) task, 4) CLIP-based automated feature-space evaluation, and 5) comparative analysis between Bradley–Terry perceptual scores and CLIP projection scores. Human evaluation and automated evaluation were performed independently and compared only during the final analysis stage.

B. Stimulus Generation

Stimulus images were generated using a Stable Diffusion-based inpainting pipeline with the Realistic Vision V5.1 Inpainting checkpoint (Realistic_Vision_V5.1-inpainting.safetensors). Generation was performed at a resolution of 512 × 512 pixels using 35 inference steps, a guidance scale of 7.5, and a denoising strength of 0.7. An initial mannequin image and a garment-region mask were used for inpainting. A randomly initialized seed was used for each generation and recorded in the corresponding generation metadata to enable traceability of the generated stimuli.

Five female garment images were manually selected from the generated candidates and used as base stimuli (Dress A–E). The selection was intended to provide visually distinct garment examples for this pilot evaluation; no formal probabilistic or stratified sampling procedure was applied. Accordingly, these five garments should be regarded as an exploratory stimulus set rather than as a representative sample of a broader garment population. The base condition was generated using the prompt "moderate drape, gentle folds clearly visible, slightly gathered at the waist." For each selected base garment, weak- and strong-drape endpoint images were subsequently generated using the same inpainting framework. The minimum-drape condition was specified using the prompt "studio product photo of a mannequin torso wearing a dress with no visible drape, smooth fitted surface, minimal folds, matte fabric, clean background," whereas the maximum-drape condition was specified as "studio product photo of a mannequin torso wearing a dress with strong drape, deep flowing folds, gathered at the waist, matte fabric, clean background." These descriptions served as operational anchors for the drape manipulation rather than as established physical definitions of minimum and maximum fabric drape.

Each generated endpoint image was encoded using the variational autoencoder (VAE) associated with the diffusion pipeline, and the resulting latent representation was stored after application of the model scaling factor. Thus, the present procedure did not employ a separate latent inversion algorithm such as DDIM inversion; instead, the generated images were re-encoded into the model's VAE latent space.

For each base garment, the stored minimum- and maximum-drape latent representations were used as the endpoints of the manipulation trajectory. Intermediate latent representations were generated by spherical linear interpolation (SLERP) between these two endpoints. Five equally spaced manipulation levels, $\alpha = -1.5$, -0.75, 0.0, 0.75, and 1.5, were used. The α values were mapped linearly onto the interpolation interval between the minimum- and maximum-drape latent representations, with $\alpha = -1.5$ and $\alpha = 1.5$ corresponding to the two endpoints and $\alpha = 0$ representing the midpoint of the interpolation trajectory. The interpolated latent representations were decoded using the VAE to produce the final 512 × 512 stimulus images. The resulting stimulus set comprised 25 images (5 base garments × 5 α levels). Representative images at $\alpha = -1.5$, 0.0, and 1.5 are presented in Fig. 2.

Before the final stimulus sequences were used for perceptual evaluation, the latent configuration was subjected to an automated quality-control procedure based on our previous evaluation framework [5]. For each base garment, the difference

between the distances from the base latent representation to the minimum and maximum endpoints (Δ) and the relative centrality of the base representation (c) along the minimum-to-maximum direction were calculated. The mean values of Δ and c across the five base garments were then used for quality-control classification. A configuration was classified as PASS when |mean Δ| < 8.0 and mean c > 0.3, and as WEAK-PASS when |mean Δ| < 12.0 and mean c > 0.15. Configurations not satisfying these conditions were classified as FAIL. These threshold values were empirically determined through iterative testing during the development of our previous evaluation framework [5] and were retained in the present study as practical quality-control criteria rather than theoretically derived universal thresholds.

Prior to deployment, all generated stimulus images were visually inspected by the authors. No images were excluded from the final stimulus set because all generated images passed this visual quality-control procedure without requiring regeneration.

C. Human Perceptual Evaluation

Fifteen participants completed the experiment. Because this study was conducted as a preliminary evaluation of the proposed pipeline, demographic information such as age, gender, and occupation was not collected. The experiment comprised ten primary comparison trials: two α intervals (−1.5 vs. 0.0 and 0.0 vs. 1.5) for each of the five base garments. One additional replicate trial of the Dress B comparison between α = 0.0 and α = 1.5 was included as a limited within-participant consistency check, resulting in 11 trials per participant. This replicate was intended only to provide a basic check of repeated responses for one comparison and was not designed as a comprehensive assessment of reliability across garments or comparison difficulty. Trial order was randomized, and the left-right presentation of each image pair was randomized. The experiment therefore yielded a total of 165 paired-comparison records.

D. CLIP-Based Feature-Space Evaluation

Following our previously proposed CLIP-based evaluation framework [5], automated feature-space evaluation was performed independently for each base garment using CLIP image embeddings. The evaluation was implemented using the OpenCLIP library with OpenAI-pretrained weights. CLIP was originally pretrained on large-scale image–text pairs; however, no text prompt was directly used to define the drape-related evaluation direction in the present analysis. Instead, as described below, the direction was defined separately for each base garment from the CLIP image embeddings of its minimum- and maximum-α endpoint images.

For each base garment, five generated images corresponding to the manipulation levels α = −1.5, −0.75, 0.0, 0.75, and 1.5 were encoded using the CLIP image encoder. Each resulting image embedding was L2-normalized before subsequent analysis.

The drape-related direction was defined separately for each base garment using the normalized CLIP image embeddings of the two endpoint stimuli. The minimum endpoint corresponds to α = −1.5, and the maximum endpoint corresponds to α = 1.5. Let $v_{b,min}$ and $v_{b,max}$ denote the normalized CLIP image embeddings of these two endpoint images, respectively. The normalized drape direction d_b was defined as follows:

$$d_b = \frac{(v_{b,max} - v_{b,min})}{\|v_{b,max} - v_{b,min}\|} \quad (1)$$

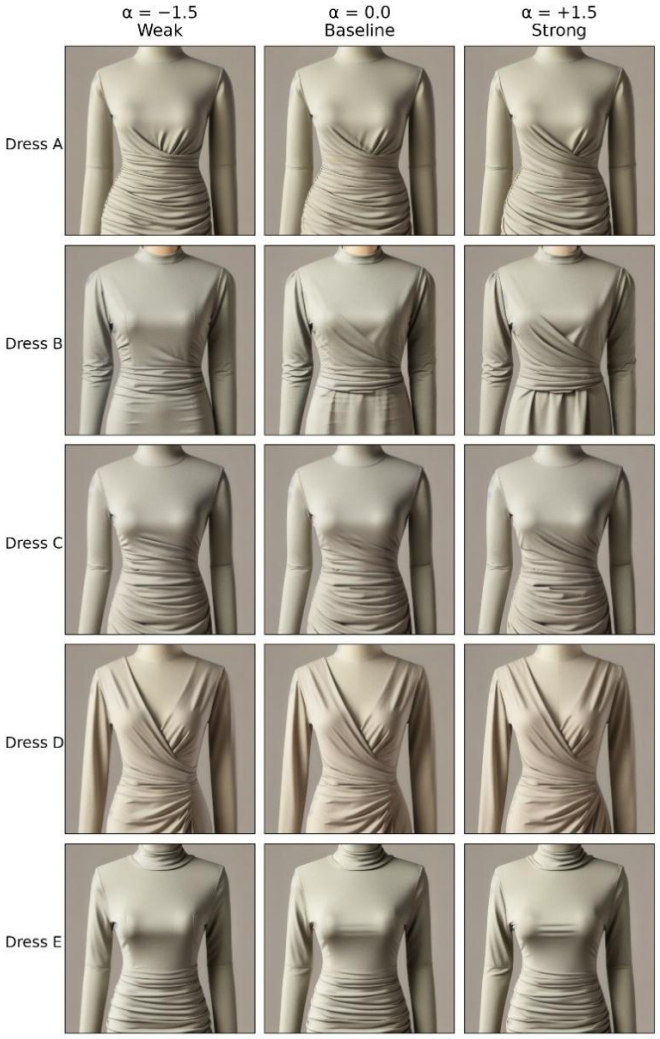

Fig. 2. Representative stimulus sequences for the five base garments (Dress A–E) at three drape manipulation levels: α = −1.5 (weak), 0.0 (baseline), and +1.5 (strong).

The midpoint between the minimum and maximum endpoint embeddings was then calculated. Let $v_{b,mid}$ denote this midpoint:

$$v_{b,mid} = \frac{v_{b,max} + v_{b,min}}{2} \quad (2)$$

For each generated image, its relative position along the drape-related direction was quantified using a CLIP projection score. Let $v_{b,\alpha}$ denote the normalized CLIP image embedding of the image generated from base garment **b** at manipulation level **α**. The CLIP projection score was calculated as follows:

$$S_{CLIP(b,\alpha)} = \left(v_{b,\alpha} - v_{b,mid}\right)^T d_b \quad (3)$$

The CLIP projection score represents the relative position of each generated image along the feature-space direction connecting the minimum- and maximum-α images of the same base garment. Importantly, this analysis does not assume that CLIP contains a predefined category corresponding to drape intensity. Instead, the drape-related direction is operationally defined for each base garment from the CLIP image embeddings of its two endpoint stimuli. Accordingly, the CLIP analysis should be interpreted as an internal feature-space consistency check of whether the intermediate stimuli progress systematically between the predefined endpoints, rather than as an independent semantic validation that CLIP recognizes drape intensity.

For each base garment, monotonic consistency between **α** and the CLIP projection score was evaluated using Spearman's rank correlation coefficient **ρ**. A positive value of **ρ** indicates that the CLIP projection score tends to increase as **α** increases.

In addition, trajectory straightness was calculated to quantify how directly the five image embeddings progressed from the minimum-α endpoint to the maximum-α endpoint in CLIP feature space. The straightness score was calculated as follows:

$$S_{str} = \frac{\|v_{b,max} - v_{b,min}\|}{\sum_{i=1}^{n-1} \|v_{b,i+1} - v_{b,i}\|} \quad (4)$$

A straightness score closer to **1** indicates that the sequence of image embeddings follows a more direct trajectory between the two endpoint embeddings.

E. Comparative Analysis

Human paired-comparison data were analyzed using the Bradley–Terry (BT) model to estimate perceptual worth scores β. The probability $P(i \succ j)$ that stimulus i (with coefficient α_i) is perceived as having stronger drape than stimulus j (with coefficient α_j) is defined as:

$$P(i \succ j) = \frac{\exp(\beta_i)}{\exp(\beta_i) + \exp(\beta_j)} \quad (5)$$

These perceptual worth scores were subsequently compared with CLIP projection scores S_{CLIP} to evaluate the agreement and potential divergence between human visual perception and automated feature-space evaluation across the manipulated drape levels.

IV. Results

A. Stimulus Quality and CLIP-Based Feature-Space Evaluation

The latent configuration satisfied the predefined PASS criteria described in Section III-B. The measured mean Δ and mean c values were −0.791 and 0.537, respectively, both comfortably satisfying the predefined PASS criteria (|mean Δ| < 8.0 and mean c > 0.3).

To examine whether the aggregate PASS classification concealed weaker configurations for individual garments, the same quality-control metrics were also examined separately for each base garment. Table I summarizes the garment-specific Δ and c values. All five garments had |Δ| < 8.0 and c > 0.3, with Δ ranging from −2.578 to 2.234 and c ranging from 0.388 to 0.596. Thus, all individual garments satisfied the corresponding numerical conditions used in the predefined aggregate QC criteria.

Visual inspection of the final stimulus set identified no images requiring regeneration or exclusion.

TABLE I. GARMENT-SPECIFIC LATENT-SPACE QUALITY-CONTROL METRICS

Dress	Δ	c
A	−1.803	0.596
B	−2.578	0.564
C	−0.649	0.544
D	−1.160	0.591
E	2.234	0.388
Mean	−0.791	0.537

Fig. 3 shows the CLIP projection scores along the base-specific directions defined by the endpoint image embeddings for the five base garments. For all five garments, the projection score increased monotonically as α increased from −1.5 to 1.5. Spearman's rank correlation coefficient between α and the projection score was ρ = 1.0 for all five image sequences.

Thus, all five generated image sequences exhibited monotonic trajectories along their respective base-specific CLIP projection directions over the evaluated α range.

B. Human Perceptual Evaluation

The 2AFC experiment yielded 165 paired-comparison records from 15 participants. The replicated Dress B comparison between α = 0.0 and α = 1.5 yielded consistent responses for 14 of the 15 participants (93.3%). Because this consistency check was based on a single replicated comparison, the value should not be interpreted as an estimate of overall within-participant reliability across the full experiment.

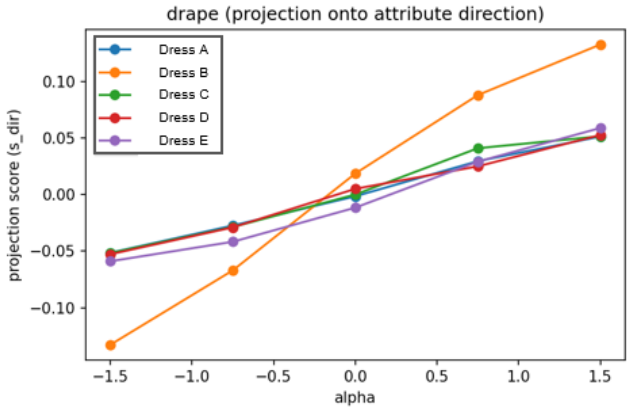

Fig. 3. CLIP-based projection scores along the drape attribute direction for five base images.

Fig. 4 shows the proportion of trials in which the higher-α stimulus was selected as having a stronger drape impression for each base garment and comparison interval. Across all base garments, the higher-α stimulus was selected in 42 of 75 comparisons (0.560) for α = −1.5 versus 0.0 and in 77 of 90 comparisons (0.856) for α = 0.0 versus 1.5.

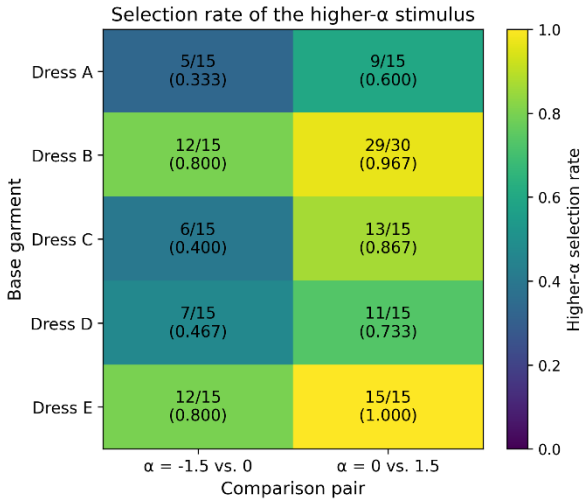

Fig. 4. Higher-α stimulus selection rates for each base garment and comparison interval in the 2AFC experiment. Each cell shows the number of higher-α selections over the number of comparisons, with the corresponding selection rate in parentheses.

The selection rates differed among the five base garments. For α = −1.5 versus 0.0, the higher-α selection rates were 0.333, 0.800, 0.400, 0.467, and 0.800 for Dresses A–E, respectively. For α = 0.0 versus 1.5, the corresponding rates were 0.600, 0.967, 0.867, 0.733, and 1.000. The neutral-to-high comparison for Dress B contained the additional replicate trial and therefore comprised 30 responses rather than 15.

The aggregated paired-comparison data were analyzed using the Bradley–Terry model described in Section III-E. The normalized BT worth values were 0.102, 0.130, and 0.768 for α = −1.5, 0.0, and 1.5, respectively, showing an aggregate monotonic ordering with α.

C. Garment-Specific Bradley–Terry Analysis

To examine variation in perceptual ordering among the individual base garments, the Bradley–Terry model was fitted separately to the paired-comparison data for each garment using the same estimation procedure as in the aggregate analysis. Table II summarizes the resulting normalized BT worth scores for the three α levels evaluated in the human perceptual experiment.

TABLE II. GARMENT-SPECIFIC BRADLEY–TERRY WORTH SCORES

Dress	α = −1.5	α = 0.0	α = 1.5
A	0.444	0.222	0.333
B	0.008	0.033	0.959
C	0.167	0.111	0.722
D	0.234	0.204	0.562
E	<0.001	<0.001	>0.999

For Dress E, the BT fit approached the boundary because the α = 1.5 stimulus was selected in all comparisons against α = 0.0; therefore, these values should be interpreted as indicating an extremely strong ordering toward α = 1.5 rather than as stable finite estimates.

The garment-specific BT worth scores differed substantially among the five base garments. Dress B exhibited a monotonic increase in BT worth across the three evaluated α levels, with values of 0.008, 0.033, and 0.959 for α = −1.5, 0.0, and 1.5, respectively. Dress E also showed a strong ordering toward the highest α level, with estimated worth values below 0.001 for α = −1.5 and 0.0 and above 0.999 for α = 1.5. As noted in Table II, the α = 1.5 stimulus for Dress E was selected in all comparisons against α = 0.0, resulting in a boundary-like BT estimate.

In contrast, the estimated BT worth scores for Dresses A, C, and D showed local reversals across the three evaluated α levels. For Dress A, the normalized worth values were 0.444, 0.222, and 0.333 for α = −1.5, 0.0, and 1.5, respectively. For Dress C, the corresponding values were 0.167, 0.111, and 0.722, and for Dress D they were 0.234, 0.204, and 0.562. Thus, α = 1.5 had the highest estimated worth for Dresses C and D, whereas the point estimate at α = −1.5 was slightly higher than that at α = 0.0. Dress A showed a different estimated ordering, with the highest worth at α = −1.5, followed by α = 1.5 and α = 0.0. Because these garment-specific BT worth values were estimated from a limited number of binary comparisons, the observed local reversals should be interpreted as descriptive, exploratory patterns rather than as statistically established violations of monotonicity.

V. DISCUSSION

A. Agreement and Divergence Between Automated and Human Evaluation

The results revealed both overall agreement and garment-specific divergence between the CLIP-based and human perceptual evaluations. In the automated evaluation, all five garment sequences exhibited monotonic CLIP projection scores across the five α levels, with Spearman's ρ = 1.0 for every base garment. Human evaluation also showed monotonic ordering at the aggregate level across the three α levels included in the human experiment, with normalized Bradley–Terry worth increasing from 0.102 at α = −1.5 to 0.130 at α = 0.0 and 0.768 at α = 1.5.

However, this aggregate agreement did not extend uniformly to the individual garments. The garment-specific BT analysis showed a clear monotonic pattern for Dress B and a strong ordering toward the highest α level for Dress E, whereas the estimated BT worth scores for Dresses A, C, and D contained local reversals across the three α levels included in the human experiment. Given the limited number of binary comparisons, these reversals should be regarded as exploratory garment-specific patterns rather than statistically established non-monotonic effects. In particular, the low-to-neutral comparison was less consistent than the neutral-to-high comparison: the higher-α stimulus was selected in 56.0% of the former comparisons and 85.6% of the latter comparisons.

These findings highlight a distinction between feature-space consistency and perceptual consistency. The CLIP-based analysis characterizes how generated images progress along a direction defined by the endpoint images in the model's feature space. Because the minimum- and maximum-α images themselves define this direction, their relative ordering is inherent in the evaluation procedure, and the resulting perfect rank correlations should not be interpreted as independent evidence that CLIP recognizes drape intensity. The informative result of this analysis is instead whether the intermediate images progress systematically and monotonically between the predefined endpoints. Such a monotonic feature-space trajectory,

however, does not necessarily imply that human observers perceive the corresponding images as an equally ordered progression of drape intensity. The garment-specific human analysis was therefore important because the aggregate results alone would have suggested substantially stronger agreement between automated and human evaluation.

B. Garment-Dependent Perceptual Effects

Although latent-space manipulation was used to vary drape with each base garment serving as a common reference, the differences among Dresses A–E suggest that the perceptual effect of the manipulation may depend on the visual context of the base garment. As illustrated by the stimulus examples in Fig. 2, the same range of α values produced visually different manifestations of drape across the five garments. Dresses B and E showed human perceptual ordering broadly consistent with increasing α, whereas the estimated BT worth scores for Dresses A, C, and D showed local reversals in at least part of the evaluated range. These patterns are descriptive and should be interpreted cautiously given the limited number of comparisons in this pilot study.

The present experiment does not establish which visual characteristics caused these garment-dependent differences or whether the manipulated perceptual impression can be attributed exclusively to drape. The operational endpoint descriptions intentionally referred to visually associated characteristics such as surface smoothness, fold depth, and gathering, and the resulting manipulation may therefore have covaried with silhouette, apparent fit, fold density, garment structure, or other visual properties. Participants were asked only to select which image exhibited a stronger sense of drape and did not independently rate these potentially correlated attributes. Accordingly, the present results should be interpreted as evaluating the operational perceptual construct of drape intensity defined in this study, rather than an isolated visual dimension that has been experimentally separated from all related garment attributes. Determining which visual cues contribute independently to perceived drape will require controlled attribute-specific evaluations in future work.

Importantly, perceptually ambiguous cases should be distinguished from generation failures. During quality control, stimuli were screened for clear generation failures and structural defects, but images were not excluded merely because the perceptual ordering of drape might be difficult to judge. Such cases are informative for the present research question because the purpose of the perceptual evaluation is precisely to determine whether technically controlled image changes produce consistent human judgments. Removing perceptually ambiguous stimuli in advance could therefore conceal cases in which automated control and human perception diverge.

C. Implications for Human-in-the-Loop Evaluation

The observed discrepancy illustrates the complementary roles of automated and human evaluation in generative fashion research. Automated feature-space analysis provides an efficient means of screening large numbers of generated image sequences and identifying systematic trajectories. In the present experiment, CLIP-based evaluation indicated monotonic progression for all five garment sequences. Human evaluation, in contrast, identified garment-specific deviations that were not apparent from the automated results alone.

This complementary relationship is central to the proposed semi-automated evaluation pipeline. The role of automation is not to replace human perceptual judgment but to reduce the effort required to generate, organize, screen, and quantitatively characterize controlled stimuli. Human evaluation can then be concentrated on determining whether technically consistent manipulations correspond to the intended perceptual effect. The pipeline therefore provides a practical mechanism for detecting cases in which model-space consistency does not translate directly into perceptual consistency.

The results also suggest a possible feedback loop for improving automated evaluation models. Garment–attribute combinations for which automated trajectories and human perceptual ordering disagree can be identified systematically and accumulated as perceptually informative cases. Such human-annotated discrepancies could potentially be used in future work to evaluate or adapt vision-language models for fashion- and textile-specific perceptual attributes. Rather than assuming that a general-purpose representation such as CLIP fully captures these attributes, the Human-in-the-Loop framework provides empirical data for determining where additional domain adaptation may be beneficial.

D. Limitations and Future Directions

Several limitations should be considered when interpreting these findings. First, this pilot study included only five AI-generated female garments and 15 participants. Because the base garments were manually selected rather than sampled according to predefined objective criteria, the present findings should not be interpreted as estimating the prevalence of such perceptual discrepancies across garment populations. The garment-specific patterns and local reversals in the estimated BT worth scores observed in the present analysis should therefore be interpreted as exploratory findings rather than as stable estimates of garment-dependent perceptual ordering. The observed garment-specific patterns cannot yet be generalized to other garment categories, designs, materials, or populations. Participant demographic information was not collected, which also prevents examination of whether perceptual judgments differed according to age, gender, fashion expertise, or other participant characteristics. In addition, the operational drape manipulation was not experimentally separated from potentially correlated visual attributes such as silhouette, apparent fit, fold density, gathering, or garment structure. Independent attribute ratings or controlled manipulations will be needed to determine the extent to which these visual factors contribute separately to perceived drape intensity.

In addition, each garment–α condition was represented by a single generated stimulus. Although the generation parameters and random seeds were recorded to ensure traceability, the present design does not distinguish systematic effects of the latent manipulation from variation associated with individual stochastic generations. The observed feature-space trajectories and perceptual judgments should therefore be interpreted as applying to the specific stimulus realizations examined in this pilot study. Future work should generate multiple independent realizations for each garment–α condition and evaluate the

robustness of both automated feature-space trajectories and human perceptual ordering across generation seeds.

The present Bradley–Terry analyses also treat the paired-comparison responses as aggregated outcomes and do not explicitly model participant-level heterogeneity or within-participant dependence across repeated judgments. Given the small number of participants and the sparse comparison structure of this pilot experiment, the garment-specific BT estimates were used primarily as descriptive summaries of perceptual ordering rather than as population-level inferential estimates. Future studies with larger samples and denser repeated-measures designs should employ hierarchical Bradley–Terry models or mixed-effects logistic regression to jointly account for participant- and garment-level variation.

Second, although five α levels were generated and evaluated using CLIP, the human 2AFC experiment evaluated only two intervals: $\alpha = -1.5$ versus 0.0 and $\alpha = 0.0$ versus 1.5. The present results therefore do not establish the detailed functional relationship between α and perceived drape intensity. In particular, the difference in selection rates between the two evaluated intervals should not be interpreted as evidence of a general nonlinear psychophysical response. The sparse comparison design also limits the stability of garment-specific Bradley–Terry estimates, particularly in cases of highly consistent choices that produce boundary-like fits. Future experiments should include a denser set of pairwise comparisons across the manipulation range.

Third, the automated evaluation used base-specific CLIP directions defined from the minimum- and maximum-α endpoint images. This procedure is useful as an internal feature-space consistency check for characterizing the relative trajectory of each generated sequence, but it does not provide an independent semantic validation of drape intensity or establish that CLIP contains an intrinsic or general representation of this attribute. Future work should therefore evaluate intermediate stimuli using independently defined directions, such as text-derived, externally learned, or held-out directions, and investigate whether fashion- or textile-specific representations provide closer correspondence with human perceptual judgments.

Finally, the present study examined only drape intensity as an operational perceptual attribute. Extending the same experimental framework to additional garment attributes, such as material appearance, glossiness, fit, or design-related variations, would help determine whether the observed automated–human discrepancies are specific to drape or represent a more general characteristic of fine-grained attribute control in generative fashion systems. Larger and more diverse perceptual datasets would also enable systematic investigation of domain-specific adaptation or additional training of vision-language models using human perceptual annotations.

In addition, the within-participant consistency check was based on only one replicated comparison (Dress B, $\alpha = 0.0$ vs. 1.5), which showed a relatively decisive selection pattern. The observed 93.3% agreement therefore cannot be generalized to more ambiguous comparisons or interpreted as an overall measure of response reliability.

VI. Conclusion

This study investigated the perceptual validity of latent-space control of garment drape intensity in AI-generated garment images using a semi-automated Human-in-the-Loop evaluation pipeline. Five base garments were manipulated across five α levels and evaluated independently using CLIP-based feature-space analysis and a human 2AFC experiment with Bradley–Terry scaling.

The CLIP-based evaluation showed monotonic trajectories for all five garment sequences, whereas human evaluation revealed a more complex pattern. Although the aggregate Bradley–Terry scores increased monotonically with α, garment-specific analysis revealed local reversals in the estimated perceptual ordering for three of the five base garments. Given the limited number of binary comparisons, these garment-specific reversals should be interpreted as exploratory patterns rather than as statistically established non-monotonic effects. These findings demonstrate that aggregate agreement between automated and human evaluation can mask stimulus-specific perceptual discrepancies and that feature-space consistency does not necessarily imply perceptual consistency.

The proposed framework provides a practical means of combining automated screening with human perceptual validation for fine-grained attributes in generative fashion systems. Future work will extend the evaluation to larger and more diverse garment and participant sets, additional perceptual attributes, and denser manipulation levels. The Human-in-the-Loop data obtained through such evaluations may also support the development or adaptation of automated models that better reflect fashion- and textile-specific human perception.

Declaration on Generative AI

Generative AI tools, including ChatGPT (OpenAI) and Gemini (Google), were used during manuscript preparation to assist with language refinement, organization, and improvement of clarity. All AI-assisted content was critically reviewed, revised, and verified by the authors. The scientific ideas, experimental design, data analysis, interpretation of the results, and conclusions presented in this study were developed and validated by the human authors, who take full responsibility for the content of the manuscript.

SGRL: A Hybrid Semantic-Graph Representation Learning Framework for Software Vulnerability Detection

Cong Bui Van
Posts and Telecommunications Institute of Technology (PTIT),
122 Hoang Quoc Viet, Nghia Do Ward, Hanoi City, Vietnam

***Abstract*—The increasing scale and complexity of software increase the risk of security vulnerabilities, creating a need for automated and effective detection methods. Transformer-based methods can learn semantic representations but do not fully exploit structural information, whereas graph neural network-based methods remain limited in representing token-level semantics. In addition, data imbalance affects models' learning and generalization capabilities. In this study, the author proposes SGRL (Semantic–Graph Representation Learning), a framework that combines CodeT5 and a Graph Convolutional Network (GCN) over a Code Property Graph (CPG) to jointly exploit the semantic and structural features of source code. The two feature sources are fused through concatenation and adjusted using BDC (Bernoulli Dropout in CNN) before classification by a Multi-Layer Perceptron (MLP). Experiments on the Verum dataset with the optimal configuration of a 512-token input length and a BDC probability of 0.2 achieve an Accuracy of 84.23%, Precision of 84.55%, Recall of 84.23%, and F1-score of 84.14%. Results on Verum and FFmpeg+Qume also show that SGRL outperforms REVEAL, Russell, VulDeePecker, SySeVR, and Devign under the corresponding experimental settings.**

***Keywords*—Source code vulnerability detection; CodeT5; graph convolutional network; code property graph; representation learning; deep learning**

I. Introduction

A. Problem Statement

In the context of digital transformation and the development of large-scale software systems, ensuring source code security is essential to minimizing the risk of vulnerability exploitation and system compromise. Programming errors such as buffer overflow, use-after-free, null pointer dereference, and out-of-bounds write can introduce serious vulnerabilities and may even lead to remote code execution [1]. Accordingly, source code vulnerability detection generally involves two main tasks: 1) extracting vulnerability-related indicators and features; and 2) analyzing these features to determine the presence of vulnerabilities [1–5]. On this basis, current source code vulnerability detection methods can be divided into two main categories: 1) rule- and pattern-based methods; and 2) machine learning- and deep learning-based methods.

1) Rule-based detection: Rule-based methods identify vulnerabilities using rules, patterns, or indicators of unsafe behavior derived from expert knowledge and known vulnerabilities. Common techniques include static analysis, pattern matching, reverse engineering, and testing. These methods have the advantages of interpretability and the ability to detect predefined types of vulnerabilities effectively. However, constructing and updating rules requires considerable expert effort; their generalization capability is limited, they are prone to false alarms, and they have difficulty detecting new types of vulnerabilities.

2) Machine learning- and deep learning-based detection: Machine learning and deep learning methods transform source code into feature representations to learn the differences between vulnerable and secure source code. The development of Transformer models such as BERT [6], RoBERTa [7], CodeBERT [8], and CodeT5 [9] has improved the ability to learn semantic and contextual representations of source code through relationships among tokens. However, these models primarily represent source code as sequences and do not directly model structural relationships such as syntax, control flow, and data dependencies.

Conversely, Graph Neural Network (GNN)-based methods can exploit program structure through graphs such as the Abstract Syntax Tree (AST) [10], Control Flow Graph (CFG) [11], Program Dependence Graph (PDG) [12], and Code Property Graph (CPG) [13]. In particular, CPG combines syntactic, control-flow, and data-flow information, enabling the model to learn dependencies among program components more comprehensively. GCN is a common GNN architecture capable of aggregating information from neighboring vertices to learn structural representations of graphs.

Nevertheless, most existing studies focus separately on semantic representation using Transformers or structural representation using GNNs, and therefore do not fully exploit the interaction between these two types of information. Furthermore, vulnerability detection data often exhibit considerable class imbalance between secure and vulnerable samples [14], increasing bias toward the majority class and affecting the ability to detect vulnerable samples. Consequently, combining semantic representations from Transformers, structural representations from GNNs, and a mechanism for mitigating the effects of data imbalance is a necessary approach to improving the effectiveness and generalization capability of source code vulnerability detection systems.

B. Research Motivation and Objectives

1) Research motivation: In recent years, deep learning methods for source code vulnerability detection have primarily developed along two directions: 1) semantic representation learning using Pre-trained Language Models (PLMs), and 2) program structural representation learning using Graph Neural Networks (GNNs) [15–18]. Models such as CodeBERT, GraphCodeBERT, CodeT5, and UniXCoder have significantly improved the semantic representation of source code. In particular, CodeT5 can learn contextual representations of tokens and statements, but it primarily processes source code as sequences and therefore does not fully exploit structural relationships such as control flow and data dependencies.

Conversely, methods based on AST, CFG, PDG, and particularly CPG combined with GCN can effectively exploit the program's structural relationships. However, the effectiveness of GCN depends substantially on the quality of the input vertex features. Methods using One-Hot Encoding, Word2Vec, FastText, or GloVe do not fully capture the contextual semantics of source code. Moreover, data imbalance remains a considerable challenge because vulnerability detection datasets often contain substantially more secure than vulnerable samples. Techniques such as Random Oversampling, SMOTE, ADASYN, and GAN can reduce imbalance but still entail risks of generating redundant samples, distorting data distributions, or causing overfitting.

These limitations indicate a remaining research gap in jointly exploiting deep semantic representations, program structural representations, and mitigation of data imbalance during representation learning. Therefore, this study proposes an architecture combining a Transformer and GCN, in which CodeT5 learns semantic features, CPG–GCN learns structural features, and a feature-rebalancing mechanism based on BDC is applied to improve generalization and source code vulnerability detection performance.

2) Proposed objectives and solution direction: To address the limitations of existing methods, this study proposes the SGRL Framework, a representation learning architecture that combines a Transformer and a graph neural network to exploit both semantic and structural information in source code. CodeT5 learns semantic representations from normalized source code, whereas CPG combined with GCN learns program structural representations. The two feature sources are then fused to construct a unified representation space for vulnerability detection.

Specifically, source code is first normalized to reduce noise and remove unnecessary components such as comments, redundant whitespace, and symbols that have no value for the representation process. The normalized source code is fed into CodeT5 to obtain fixed-dimensional semantic representations. Simultaneously, the source code is converted into a Code Property Graph (CPG), in which vertices represent program components and edges describe syntactic, control-flow, and data-flow relationships. Graph features are propagated and aggregated through GCN layers to learn program structural representations.

C. Principle of Source Code Vulnerability Detection of the SGRL Framework

Recent studies indicate that exploiting semantic or structural features in isolation is insufficient for a comprehensive source code representation because programs simultaneously contain semantic, syntactic, control-flow, and data-flow information. Therefore, combining the two types of representations is necessary to improve vulnerability detection effectiveness.

On this basis, this study proposes the SGRL Framework, which combines CodeT5 and GCN to jointly learn semantic and structural features of source code. CodeT5 extracts semantic representations, whereas GCN learns structural representations from CPG. The two feature vectors are fused by concatenation to form a combined representation space used as input to the vulnerability classification stage.

D. Contributions of the Study

Based on the limitations of existing methods, this study proposes the SGRL Framework, which combines a pre-trained language model and a graph neural network to jointly exploit semantic and structural features while mitigating the effects of data imbalance. The main contributions are as follows:

First, an architecture combining CodeT5 and GCN is proposed to jointly learn semantic features from source code and structural features from CPG, thereby constructing a more comprehensive representation for vulnerability detection.

Second, a parallel representation learning process is developed in which CodeT5 learns context-rich semantic representations, whereas GCN learns structural relationships through CPG, including syntactic, control-flow, and data-flow information.

Third, a feature-fusion mechanism based on concatenation is proposed to preserve both representation sources before they are passed to the classifier, thereby enhancing the ability to exploit relationships between semantic and structural information.

Fourth, this study proposes a new data-balancing method called BDC, based on generating data for the minority class through the Bernoulli distribution in the Dropout layer of a CNN. BDC balances the minority and majority classes in the experimental dataset. Applying BDC after feature fusion aims to enhance the model's generalization capability under imbalanced-data conditions. Unlike traditional data generation methods, BDC acts as an overfitting-reduction technique: this study exploits random feature removal according to a Bernoulli distribution to generate multiple representation combinations during training. This approach helps limit the model's dependence on a few dominant features while improving representation learning for minority-class samples without using synthetic sample generation techniques such as SMOTE [19] or GAN [20].

Fifth, experiments are conducted on the Verum dataset using different token-length and BDC-probability configurations. The best result is obtained with 512 tokens and BDC = 0.2, yielding an accuracy of 84.23%, Precision of 84.55%, Recall of 84.23%, and an F1-score of 84.14%, demonstrating the effectiveness of combining semantic–structural representations with a feature-adjustment mechanism for source code vulnerability detection.

II. Related Works

A. Rule-Based Source Code Vulnerability Detection

According to Chen et al. [21], rule-based vulnerability detection is a traditional approach commonly used in static source code analysis tools. This method constructs rules or source code patterns from expert knowledge and known vulnerability types, and then compares source code against the rule set to identify indicators of potential information security risks [22]. Representative tools such as Flawfinder, Cppcheck, Clang Static Analyzer, SonarQube, and Fortify SCA typically rely on secure coding rules and knowledge bases such as CWE [23] and CERT C/C++, enabling detection of several common vulnerability types, including buffer overflows, invalid pointer use, and memory leaks.

In addition, Liu et al. [3] proposed VulMatch to detect recurring vulnerabilities (1-day and N-day) by combining source code and binary information. Experiments on open-source projects showed that VulMatch performed better than some binary matching methods, such as Asm2vec [24] and Palmtree [25], while also providing explainable detection results. However, the method still encounters difficulties when processing large-scale, complex source code or incompletely labeled data.

In general, rule-based methods offer interpretability and effectiveness for known vulnerability types, but are limited in generalization and the detection of new vulnerability types. Detection effectiveness depends substantially on the completeness of the rule set and typically requires manual updates when new vulnerability types or programming techniques emerge. Furthermore, rules are primarily based on syntactic patterns and therefore do not fully exploit program semantics, control flow, and data flow, resulting in risks of false alarms and missed vulnerabilities, particularly for source code with complex structures. These limitations have encouraged the development of machine learning and deep learning methods capable of automatically learning representations and generalizing vulnerability features from data.

B. Source Code Vulnerability Detection Based on Natural Language Processing

Advances in machine learning and deep learning have introduced new approaches to source code vulnerability detection, enabling models to learn features automatically from data rather than relying on manually constructed rules. Early methods employed Bag-of-Words (BoW), TF-IDF, Word2Vec [26, 27], and FastText in combination with algorithms such as SVM, Random Forest, or XGBoost. However, these representations primarily reflect statistical relationships among tokens and do not fully exploit contextual information or dependencies within programs.

The emergence of source code language models such as CodeBERT, CodeGPT, and CodeT5 has substantially improved semantic representation learning. Ding et al. [28] showed that evaluation results for source code language models may be affected by duplication and data leakage, while these studies have not fully addressed complex structures and relationships beyond the scope of a single function. Kalouptsoglou et al. [29] further investigated transfer learning with CodeGPT and CodeBERT, showing that token-level contextual representations are effective; however, these methods still primarily exploit sequential representations and do not directly integrate structural information such as control flow and data dependencies.

Recently, Zhang et al. [30] proposed CodeSAGE, which combines Code Attribute Graph–GraphSAGE with BiLSTM and Attention to jointly exploit structural and semantic features. Although positive results were achieved, the method has not exploited source code-specific pre-trained language models such as CodeT5 or directly fused semantic representations from Transformers with structural representations from CPG/GCN. These limitations highlight the need to develop models capable of deeper integration between program semantics and structure, providing a basis for the approach proposed in this study.

C. Source Code Vulnerability Detection Based on Graph Structure

To overcome the limitations of methods that exploit only sequential representations, numerous studies have shifted toward graph-based source code representations, particularly AST, CFG, PDG, and CPG. AST describes syntactic structure; CFG represents control flow; and PDG models data and control dependencies. Yamaguchi et al. [13] proposed the Code Property Graph (CPG), which jointly models syntactic information, control flow, and data dependencies within a unified graph structure, thereby providing a more comprehensive representation of program structure and behavior.

On this basis, GNN architectures such as GCN, GGNN, GAT, and Graph Transformer have been applied to learn structural representations for vulnerability detection. Liu et al. [31] proposed Vul-LMGNNs, reporting positive results on the REVEAL and SARD datasets compared with Devign [32], LineVD [33], and FUNDED [34]. Subsequent studies, including iGnnVD [35], Adaptive GNN [36], and Heterogeneous GNN [37], further exploited diverse relationships and features in program graphs. In addition, VulMPFF [38] combines source code sequence information, lexical–syntactic relationships, and graph structure, achieving improved results over several existing methods. Studies by Cong et al. [39, 40] also indicate that combining Transformers and GNNs has the potential to improve representation learning by jointly exploiting semantic and structural source code information.

However, GNN-based methods still exhibit several limitations. First, representation learning effectiveness depends considerably on the quality of initial node features; methods using One-Hot Encoding, Word2Vec, or GloVe do not fully reflect the contextual semantics of source code. Second, many studies focus on graph-based information propagation without effectively exploiting pre-trained language models to enhance node-level semantic representations. Consequently, such models may capture structural relationships well but remain limited in distinguishing code segments with similar structures but different semantics and security properties. This indicates the need to combine pre-trained language models with GNNs to construct more comprehensive semantic–structural representations for source code vulnerability detection.

III. PROPOSED MODEL

A. Architecture of the SGRL Model

Overall, the SGRL Framework consists of five main stages: 1) source code normalization; 2) semantic representation learning; 3) structural representation learning; 4) feature fusion and rebalancing; and 5) vulnerability classification. The entire processing pipeline is illustrated in Fig. 1.

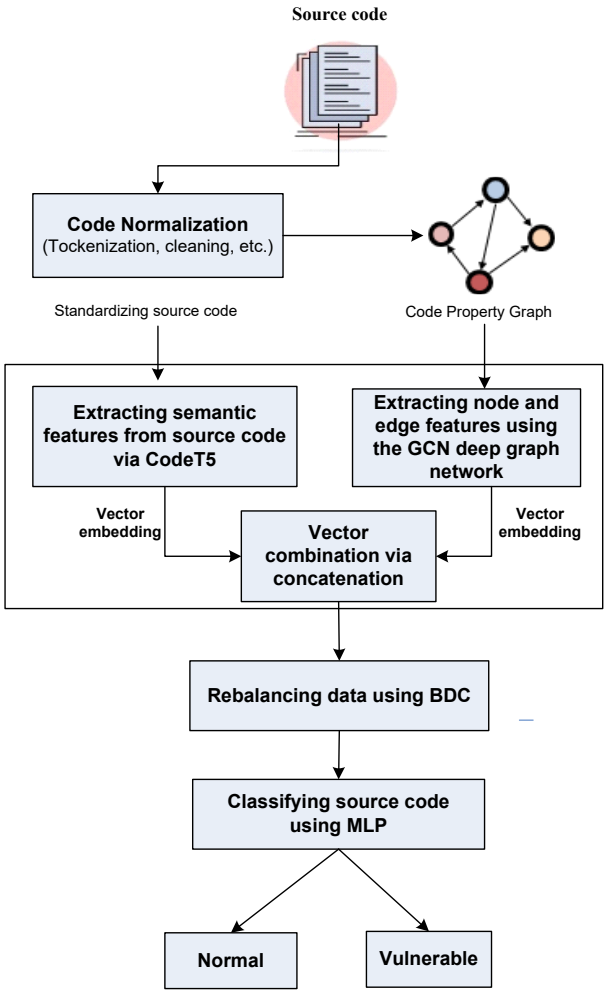

Fig. 1. Overall architecture of the SGRL framework.

The functions, tasks, and operating process of the blocks in the SGRL model are as follows:

- "Source code": The source code dataset used is Verum [41], written in C/C++.
- "Code Normalization" block: Removes redundant data and comments, searches for and checks erroneous source code segments, and removes them from the source code.
- "Code Property Graph" block: Analyzes and transforms the source code into CPG form using the Joern tool [42]. Joern analyzes source code in terms of syntax and semantics to represent it as a CPG graph.
- "Extracting semantic features from source code via CodeT5" block: Extracts semantic features of the source code, including features of individual nodes or of the entire code segment.
- "Extracting node and edge features using the GCN deep graph network" block: Extracts source code features from the CPG graph.
- "Vector combination via concatenation" block: Fuses two feature vectors—semantic source code features extracted using CodeT5 and structural features extracted from the graph using GCN—through concatenation.
- "Rebalancing data using BDC" block: After the source code feature profiles are obtained, the authors observe a very large difference between the numbers of normal source code features and vulnerable source code features. Immediate classification may result in inaccurate predictions or, in some cases, model overfitting. Therefore, this study proposes generating data from the minority class to balance the experimental dataset using BDC. The result is a new dataset containing source code feature profiles balanced between the vulnerable and non-vulnerable labeled classes.
- "Classifying source code using MLP" block: Detects and classifies source code vulnerabilities based on the features constructed by the "Vector combination via concatenation" block. The author proposes using MLP for source code vulnerability classification.

The above describes the operation of the blocks in Fig. 1. The following sections describe the model's source code vulnerability detection task in detail.

B. Data Preprocessing

1) Source code normalization: In the first stage, source code is preprocessed and normalized to remove redundant components such as comments, whitespace, and unnecessary characters; at the same time, variable names, function names, and parameters are standardized according to a unified rule. This process helps reduce vocabulary diversity, limit sparse data, and improve the model's generalization capability. Preprocessing is necessary because raw source code contains many symbols, complex syntax, and differences in programming style, making the representation learning process difficult.

2) Representing source code as a CPG graph:

a) Introduction to CPG: CPG, introduced by Fabian Yamaguchi et al. in 2014 [13], combines AST, CFG, and PDG into a common data structure consisting of nodes and node types representing source code components such as classes and methods; labeled directed edges representing relationships among components; and key–value pairs containing node attributes, where valid keys depend on the node type. In this study, the author proposes normalizing and converting source code into CPG form to facilitate feature extraction.

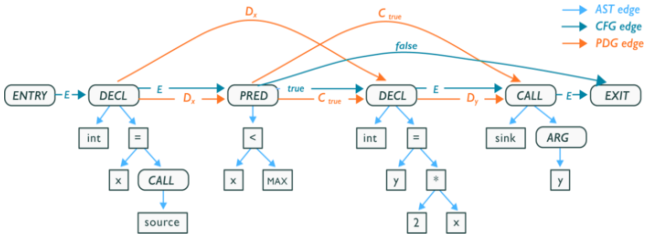

Fig. 2. Representation of source code according to CPG.

Fig. 2 shows that CPG is the combination of AST, CFG, and PDG, helping provide more important information for source code feature extraction because these graphs describe both static features (variable names, functions, etc.) and their relationships.

b) Introduction to the Joern platform: Joern [43] is a platform commonly used today in static analysis for source code, including C/C++ source code. It enables vulnerability detection by converting source code into a CPG through nodes (functions, statement blocks, etc.) to describe source code features. This study applies the Joern tool to represent C/C++ source code as a CPG graph consisting of nodes containing syntactic code snippets and syntactic edges (AST), control edges (CFG, PDG), thereby expressing all properties of the source code.

C. Source Code Feature Extraction

From Fig. 1, combining representation learning using a Transformer model and a graph neural network to jointly exploit semantic and structural source code information is an approach intended to maximize the use of different source code feature components. After normalization, the source code is processed in parallel along two directions: 1) the first branch passes it through CodeT5 to learn semantic representations at the token and statement levels; 2) the second branch represents the normalized source code as a CPG graph and then learns graph features using GCN. Regarding the second branch, studies [13, 40, 41, 43] have listed the vertex and edge features of CPG. CPG is a particularly useful representation of original code because it provides a compact, integrated representation comprising elements of control-flow and data-flow graphs, in addition to AST and the Program Dependence Graph (PDG). Each of these elements provides additional context about the overall semantic structure of the code [13]. Formally, CPG is denoted by G = (V, E), where V represents graph vertices (or nodes) and E represents edges. Each vertex in CPG comprises a vertex type (e.g., ArithmeticExpression or CallStatement) and a segment of original code. Each edge contains information about its edge type (e.g., IS_AST_PARENT or FLOWS_TO) [42].

The semantic and structural features extracted by CodeT5 and GCN, respectively, are fused through concatenation to form a combined feature vector for the subsequent classification stage. This is an entirely new proposal for source code feature extraction that uses a model combining semantic and structural representation learning, rather than focusing on a single feature type as is currently common. With this new proposal, important source code features can be extracted more comprehensively. The following sections describe the source code feature extraction process based on CodeT5 and GCN in detail.

1) Extracting semantic features of source code using CodeT5

a) Overview of CodeT5: In 2021, Wang et al. proposed CodeT5 [9], an Encoder-Decoder Transformer model pre-trained specifically for source code. Unlike previous models such as CodeBERT, which use only an Encoder architecture, CodeT5 is designed to support both code understanding and code generation tasks through a unified architecture. In particular, CodeT5 introduces an Identifier-aware Pre-training mechanism, allowing the model to learn the semantic roles of identifiers in programs, thereby significantly improving the quality of source code representation across many tasks such as bug detection, vulnerability detection, clone detection, and code generation.

After that, CodeT5 uses the Multi-Head Self-Attention mechanism to model relationships among all tokens in the code segment. For each attention head, the three matrices Query, Key, and Value are computed as follows:

$$Q = X\mathrm{W}_Q, K = X\mathrm{W}_K, V = X\mathrm{W}_V, \quad (1)$$

where, WQ, WK, and WV are weight matrices to be learned. The attention weight is determined according to Eq. (2) below:

$$Attention(Q,K,V) = Soft\max\left(\frac{QK^T}{\sqrt{d_k}}\right)V, \quad (2)$$

where, dk is the dimension of the key vector.

b) Method for extracting semantic features of source code using CodeT5: After normalization, the source code is simultaneously fed into two independent representation learning branches. The first branch uses CodeT5 to exploit the semantic features of the program. In this branch, CodeT5, a Transformer model pre-trained on a large volume of multilingual source code, can learn contextual representations that reflect the meaning of each token as well as the relationships among statements in the program. The output of CodeT5 is a fixed-dimensional semantic representation vector that reflects the content and context of the entire source code segment.

It can be said that the process of extracting semantic features of source code using CodeT5 is described in the following figure:

From Fig. 3, it can be seen that the semantic feature extraction process is performed through the following steps:

Step 1: After normalization, each code segment is represented as a token sequence according to Eq. (3) below:

$$S = \{t_1, t_2, ..., t_L\}, \quad (3)$$

Step 2: Here, L is the number of tokens after normalization. The token sequence is fed into the encoder of CodeT5. Each token is first mapped into an embedding vector in a d-dimensional feature space, as shown in Eq. (4):

$$E = \{e_1, e_2, \ldots, e_L\}, e_i \in \mathbb{R}^d. \quad (4)$$

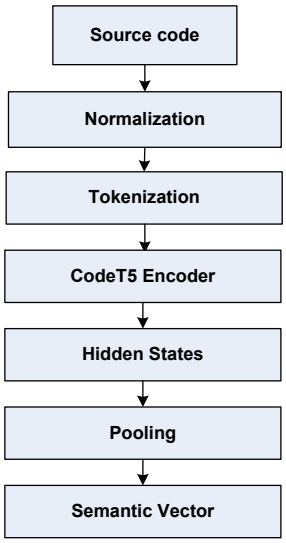

Fig. 3. The process of extracting semantic features of source code using CodeT5.

Step 3: To preserve information about the order of token occurrence, the positional vector is added to the input embedding vector:

$$X = E + P, \tag{5}$$

where, P is the positional embedding matrix.

Thanks to this mechanism, the representation of each token is updated based on the context of the entire code segment instead of depending only on neighboring tokens. This is especially useful in vulnerability detection, where the cause of a vulnerability may arise from interactions among statements located far apart. The output of the encoder is the semantic representation matrix shown in Eq. (6) below:

$$H_s = \{h_1, h_2, \ldots, h_L\} \in \mathbb{R}^{L \times d}, \tag{6}$$

where, each vector h_i contains the contextual semantic information of the i-th token.

Step 4: To obtain a fixed representation for the entire code segment, pooling can be applied, for example, averaging over all tokens according to Eq. (7):

$$Z_s = \frac{1}{L}\sum_{i=1}^{L} h_i, \tag{7}$$

where, $Z_s \in \mathbb{R}^d$ is the semantic feature vector of the code segment.

In the SGRL model, the vector Z_s is not used directly for classification but serves as one representation learning branch. In parallel with semantic representation learning using CodeT5, the other branch, also from the normalized source code segments, is represented through a CPG graph and then fed into the GCN network to extract the structural features of the program. The two feature vectors obtained from these two representation learning branches are fused through Concatenation, forming a multi-source representation that integrates both semantic information and structural information. This fused representation serves as the input for the subsequent stages of the model to improve the ability to detect vulnerabilities in source code.

2) Extracting source code features using GCN

a) Overview of GCN: GCN, developed by Thomas Kipf and Max Welling [32], is a variant of Graph Neural Networks (GNNs). A characteristic of GCN is that it uses local spectral filters on graphs to extract graph substructures and thereby reveal graph structure. In terms of its operating principle, the convolution operation in a GCN layer extracts features from neighboring components, similarly to a CNN layer [32, 44]. However, because CNNs do not work well on non-Euclidean datasets, GCN architectures seek to extract attributes from adjacent vertices. GCN is also applied in several fields, such as node classification [45], link prediction [46], graph classification [47], and graph embedding [44]. Eq. (8) below presents the propagation of representative attributes in a GCN layer.

$$H^{(l+1)} = \sigma(\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}H^{(l)}W^{(l)}) + H^{(l)} \tag{8}$$

Where:

A: The adjacency matrix of the graph,

X: The input attribute matrix of the node,

$\tilde{D}$: the degree matrix corresponding to $\tilde{A}$,

I: The identity matrix of size N x N,

$\tilde{A} = A + I$,

$\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}$: The symmetrically normalized combination of the adjacency matrix,

$W^{(l)}$: the learned weight matrix of layer l,

σ: A nonlinear function applied element-wise,

$H^{(l)}$: The output of layer l,

$H^{(0)} = X$.

b) Method for extracting features of the CPG graph based on GCN: In this study, the author selects three main components that describe the structure and information of the CPG graph and also serve as the three inputs to the proposed training model: the adjacency matrix, the node attribute matrix, and the edge attribute matrix. This information is then fed into the GCN model for processing, whose general architecture is shown in Fig. 4.

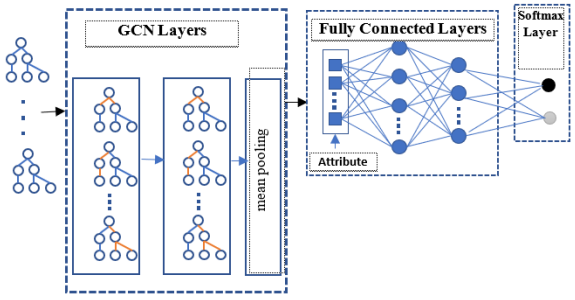

Fig. 4. Architecture of the GCN model.

From Fig. 4, it can be seen that the GCN network architecture performs feature extraction as follows:

- GCN layer: includes GCN layers and a pooling layer to extract graph features. Thus, with the behavior profile as input, the GCN network extracts the characteristics of the graph linking the processes. The output of the GCN layer is hidden representative attributes that show the connections among vertices in the graph through GCN layers. For example, in the case of using two GCN layers, the first GCN layer has the task of considering neighboring vertices of each vertex to update the attributes of that vertex. Next, the second GCN layer recursively updates the attributes of the vertices in the graph. In practice, more than two GCN layers can be used; however, study [44] indicated that only two GCN layers may still ensure a balance between effectiveness and analysis and processing time.
- Fully connected layer: this layer is similar to an MLP network and has the task of learning the attributes processed through the GCN layers.
- Softmax layer: this layer has the task of computing the probabilities of the output labels. The file being predicted is assigned to the class with the highest probability.

3) Building the source code feature vector: After the representation learning stage, the model obtains two complementary feature vectors, including semantic features from CodeT5 and structural features from GCN on CPG. The semantic features reflect the context and relationships among tokens, while the structural features represent syntactic relations, control flow, and data flow. Combining these two feature sources creates a more comprehensive source code representation, effectively supporting the vulnerability detection process.

Assume that $Z_s \in \mathbb{R}^{d_s}$ is the semantic feature vector created by CodeT5 and Z_g is the structural feature vector generated by GCN. The source code feature vector is built by concatenation along the feature dimension as follows:

$$Z = Concat(Z_s, Z_g) = [Z_s; Z_g], \quad (9)$$

Where:

- d_s is the dimension of the semantic feature vector;
- d_g is the dimension of the structural feature vector;
- $Z \in \mathbb{R}^{d_s+d_g}$ is the fused feature vector.

Thus, Concatenation is used to fuse both semantic and structural features of source code. Compared with addition or averaging, Concatenation preserves complete information from the two representation spaces without losing their distinctive features. The fused vector is then fed into subsequent learning layers so that the model can automatically determine the contribution level of each feature type during optimization.

D. Data Rebalancing

After constructing the feature profiles, direct classification may be affected by data imbalance because the numbers of samples in the vulnerable and non-vulnerable classes differ substantially. Traditional methods such as SMOTE and GAN can be used to balance data, but sample generation based on neighborhood relationships in feature space is not entirely suitable for the characteristics of source code data. Therefore, this study proposes a rebalancing mechanism based on BDC to increase the diversity of minority-class representations and reduce the impact of data imbalance during training. Accordingly, for the vector representation, each component becomes: $x = (x_1, x_2, \dots x_m) x_h (h = 1, 2, \dots m)$

$$\widehat{x_h} = a_h \, . \, x_h \quad (10)$$

where, $a_h \sim P$ is the variable is a random variable with a Bernoulli distribution [48]:

$$P(a_h) = \begin{cases} 1-p, & a_h = 0 \\ p \ , & a_h = 1 \end{cases} \quad (11)$$

It can be seen that, in the problem of generating data for the minority class (i.e., the vulnerable class), the Bernoulli distribution will:

- Generate a random value according to the Bernoulli distribution
- Return a result of 0 (non-vulnerable) or 1 (vulnerable)
  - With probability p, it takes the value 1
  - With probability $1 - p$, it takes the value 0

The algorithm below describes the data generation process using BDC.

Algorithm 1: Data balancing using BDC

Input: Feature -$feature$
Label -$label$
Rate -α
Number of generated samples based on minority class -n
$D = \{\}$
Output: $D_{balance}$
Function:$BDC(feature, label, \alpha = 0.1, n = 10)$:
for $f_i, l_i \in feature, label$ do:
if l_i $of\ minority\ class$ do:
for $t := 1$ to n do:
$f'_i \leftarrow generate\_minority\ class\_with\_rate(\alpha)$
$Add\ \ f'_i\ \ in\ D$
end
end
end
return $D_{balance}$
end

From Algorithm 1, it can be seen that:

Step 1: Search for the features of the minority class

Step 2: Iterate through the features of the minority class and apply the Bernoulli generation function to generate data for the minority class.

Step 3: Add the generated data to the original data

E. Source Code Vulnerability Classification

After the representation learning stage, the model obtains a fused feature vector integrating semantic information from CodeT5 and structural information from GCN. This vector is fed into an MLP to classify the source code into two classes: vulnerable and non-vulnerable. MLP learns a nonlinear mapping function from the feature space to the label space, thereby exploiting complex relationships among features and determining the class of the input sample.

Assume that the fused representation vector after the representation learning stage is denoted as:

$$h^* \in \mathbb{R}^d \tag{12}$$

where, d is the feature-space dimension. This input is fed through the hidden layers of the MLP. At the l-th hidden layer, the output is determined according to the equation:

$$h^{(l+1)} = \Phi\left(\mathrm{W}^{(l)} h^{(l)} + b^{(l)}\right), \tag{13}$$

Where:

- $\mathrm{W}^{(l)}$ is the weight matrix of the l-th layer;
- $b^{(l)}$ is the bias vector;
- $\Phi(\cdot)$ is the nonlinear activation function; in this study, the ReLU function is used and defined as:

$$\Phi(x) = \max(0, x) \tag{14}$$

Using multiple hidden layers helps the model learn nonlinear relations between semantic features and structural features, thereby increasing the ability to distinguish vulnerable source code samples from normal source code samples.

After the last hidden layer, the feature vector is mapped to the output layer, whose number of nodes equals the number of classes to be classified. In the source code vulnerability detection problem, the number of output classes is two, corresponding to two labels:

$$y = \{0, 1\} \tag{15}$$

Where:

- 0: the code segment does not contain a vulnerability;
- 1: the code segment contains a vulnerability.

The output logits of the model are computed according to the equation:

$$o = W_o h^{(L)} + b_0 \tag{16}$$

where, W_o are b_0 are the weight and bias of the output layer, respectively.

To convert the logits into predicted probabilities for each class, the model uses the softmax function:

$$P(y = i|x) = \frac{exp(o_i)}{\sum_{j=1}^{2} exp(o_j)}, i\epsilon\{0, 1\}, \tag{17}$$

Where:

- o_i: is the logit of the i-th class;
- $P(y = i|x)$: is the probability that the code segment belongs to class i.

The final predicted label is determined according to the maximum-probability criterion:

$$\hat{y} = \arg\max_i P(y = i|x) \tag{18}$$

During training, the parameters of the entire model are optimized by minimizing the Cross-Entropy loss function, defined as follows:

$$\mathrm{L} = -\sum_{i=1}^{2} y_i \,.\, log\ P(y = i|x) \tag{19}$$

Where:

- y_i: is the actual label of the i-th class;
- $P(y = i|x)$: is the probability predicted by the model.

The optimization process is performed by the Adam algorithm, in which the model parameters are updated in the direction of decreasing the value of the loss function on the training dataset. Thanks to its effective optimization capability for deep learning models, Adam helps speed up convergence and improve stability during training.

Through the combination of semantic representation from CodeT5, structural representation from GCN, and the MLP classifier, the model can learn distinguishing features of vulnerable samples even when they appear in many different forms in source code. At the same time, using an MLP allows the model to effectively exploit nonlinear interactions among the fused features, contributing to improving the accuracy of the source code vulnerability detection problem.

IV. Experiments and Evaluation

A. Experimental Dataset

Table I presents statistics on the experimental datasets proposed for use in the study.

TABLE I. Experimental Data Statistics

	Total number of samples	Number of vulnerabilities	Number of normal samples
Verum Dataset [41]	18169	1658	16511
FFmpeg+Qume Dataset [49]	25905	11804	14101

The Verum dataset [41] is built from open-source projects with CVE-coded vulnerabilities [50], in which code regions

containing vulnerabilities are labeled as vulnerable and safe regions are labeled as non-vulnerable. Verum supports research on vulnerability detection in C/C++ source code. Study [41] shows that this dataset has a large imbalance between security vulnerability data and normal data, with a small code duplication rate of about 0.6%, and is therefore suitable for the code vulnerability classification task.

To demonstrate the effectiveness of the proposed model, the study evaluates it using the two main datasets summarized in Table I.

B. Experimental Scenarios and Evaluation Criteria

1) Experimental scenarios: To demonstrate the effectiveness of the proposed model, the author conducts the following experimental scenarios:

a) Scenario 1: How effective is the author's proposed method in classifying source code vulnerabilities?

b) Scenario 2: Evaluation of the role of the individual components in the author's proposed model. Through this, it is confirmed whether the author's proposed method is more effective than the separate approach of each component in the proposed model on the same experimental dataset.

c) Scenario 3: Comparing the SGRL model with several other approaches on the same experimental dataset.

2) Evaluation criteria: To evaluate effectiveness, the study uses several metrics:

$$accuracy = \frac{TP + TN}{TP + TN + FP + FN} \times 100\% \quad (20)$$

$$precision = \frac{TP}{TP + FP} \times 100\% \quad (21)$$

$$Recall = \frac{TP}{TP + FN} \times 100\% \quad (22)$$

$$F1 - score = \frac{2 \times precision \times Recall}{precision + Recall} \times 100\% \quad (23)$$

Where:

- Accuracy: The proportion of correctly classified samples over the total number of samples. Accuracy is calculated according to (20).
- Precision: The proportion of TP over (TP + FP), reflecting precision when predicting positive (21).
- Recall: The proportion of TP over (TP + FN), indicating the ability to correctly detect positive samples (22).
- F1-score: The harmonic mean of Precision and Recall; the higher it is, the better the classifier (23).

C. Experimental Result on the Proposed Model

1) Experimental results of Scenario 1: In this experimental scenario, the author conducts experiments on the Verum dataset. Through the dataset description in Section IV, Part A, study [41] also confirmed that this dataset is very suitable for application to security vulnerability classification tasks. Table II below presents statistics on the effectiveness of the proposed method in security vulnerability detection based on several criteria defined in Section IV-B-2.

TABLE II. EXPERIMENTAL RESULTS OF SCENARIO 1

BDC	GCN_CodeT5											
	128				256				512			
	Acc	Pre	Rec	F1	Acc	Pre	Rec	F1	Acc	Pre	Rec	F1
0.1	81.85	81.95	81.85	81.79	82.59	82.67	82.59	82.55	83.48	83.81	83.48	83.39
0.2	82.59	82.74	82.59	82.53	83.04	83.18	83.04	82.98	**84.23**	**84.55**	**84.23**	**84.14**
0.3	82.29	82.41	82.29	82.24	82.89	83.04	82.89	82.83	84.08	84.34	84.08	84.0

From the experimental results of Scenario 1 in Table II, the model combining GCN and CodeT5 with an input length of 512 tokens and a BDC probability of 0.2 is the most suitable configuration among the parameters investigated. This configuration achieves an accuracy of 84.23%, Precision of 84.55%, Recall of 84.23%, and F1-score of 84.14%, attaining the highest values for all four evaluation metrics. The results indicate that increasing the token sequence length to 512 enables the model to exploit the semantic context of source code more effectively, while a BDC probability of 0.2 provides an appropriate degree of regularization for representation learning. Increasing the BDC probability further to 0.3 leads to a slight decline in performance, indicating that excessive feature removal may discard useful information. Therefore, combining a token length of 512 with BDC = 0.2 is the optimal configuration, yielding the best and most consistent results across all the evaluation metrics of the proposed model. This is also scientifically reasonable because, according to the survey presented in this study and the study by Chakraborty et al. [41], as many as 70% of the source code files in the Verum dataset have lengths greater than 256 and less than 512. Accordingly, selecting a token length of 512 yields the best model performance.

Fig. 5 presents the confusion matrix calculated for the proposed model with a token length of 512 and a BDC probability of 0.2.

Thus, although the Verum dataset exhibits severe class imbalance, with secure source code accounting for approximately 90.88%, the SGRL model under the 512/0.2 configuration demonstrates superior identification capability by correctly detecting 1,397 of the 1,658 actual vulnerable samples (Recall = 84.23%). Meanwhile, the number of false positives (FP) remains very low (255 samples out of a total of 16,511 secure samples), maintaining Precision at 84.55% and minimizing the cost of manual code inspection in practice.

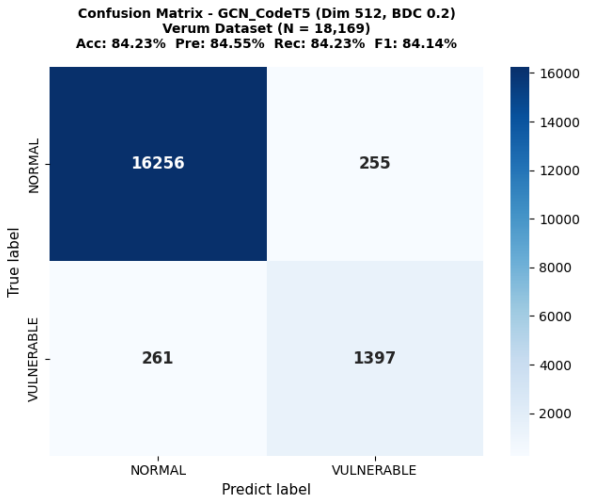

Fig. 5. Confusion matrix values of the proposed SGRL model.

2) Experimental results of Scenario 2: In this scenario, to demonstrate the effectiveness of the proposed model, the author conducts experiments on each component of the proposed model to prove that the combination of the GCN deep graph network with CodeT5 gives the best result.

First, the author conducts an experiment using only CodeT5 to extract source code features, combined with BDC to rebalance the vulnerable and non-vulnerable labels in the experimental dataset. The resulting features are then passed through a Multi-Layer Perceptron (MLP) feedforward neural network to classify source code as vulnerable or non-vulnerable.

Table III shows that, when the model is evaluated using individual components—in this case, using only CodeT5 for source code feature extraction—the resulting architecture performs considerably worse than the model proposed in this study. Specifically, at the same configuration of a 512-token input length and BDC probability of 0.2, which yields the best results among the investigated token lengths of 128, 256, and 512 and their corresponding BDC probabilities, the Accuracy, Precision, Recall, and F1-score are lower than those of the proposed model by 0.9%, 1.11%, 0.9%, and 0.85%, respectively.

TABLE III. EXPERIMENTAL RESULTS WHEN USING ONLY THE CODET5 MODEL FOR SOURCE CODE FEATURE EXTRACTION

BDC	CodeT5											
	128				256				512			
	Acc	Pre	Rec	F1	Acc	Pre	Rec	F1	Acc	Pre	Rec	F1
0.1	81.55	81.56	81.55	81.53	82.14	82.15	82.14	82.15	82.44	82.49	82.44	82.41
0.2	81.55	81.56	81.55	81.53	82.14	82.15	82.14	82.15	**83.33**	**83.44**	**83.33**	**83.29**
0.3	81.55	81.56	81.55	81.53	82.14	82.15	82.14	82.15	82.44	82.49	82.44	82.41

In the second case, the same configuration is retained, but the source code feature extraction method is changed by replacing the combined GCN and CodeT5 components with the CodeBERT model. Experiments using token lengths of 128, 256, and 512 and corresponding BDC probabilities of 0.1, 0.2, and 0.3 yield the results shown in Table IV below:

TABLE IV. EXPERIMENTAL RESULTS WHEN USING ONLY THE CODEBERT MODEL FOR SOURCE CODE FEATURE EXTRACTION

BDC	CodeBERT											
	128				256				512			
	Acc	Pre	Rec	F1	Acc	Pre	Rec	F1	Acc	Pre	Rec	F1
0.1	82.59	83.04	82.59	82.47	83.93	84.25	83.93	83.84	82.44	82.91	82.44	82.31
0.2	82.74	83.37	82.74	82.58	82.44	82.82	82.44	82.33	**92.59**	**82.91**	**82.95**	**82.49**
0.3	82.44	82.78	82.44	82.34	82.74	82.93	82.74	82.67	82.59	82.6	82.59	82.59

Table IV indicates that the best result is obtained with a token length of 512 and a corresponding BDC probability of 0.2. However, when GCN combined with CodeT5 is used for source code feature extraction, the results are considerably better in terms of Precision, Recall, and F1-score, by 1.64%, 1.28%, and 1.65%, respectively. Only the Accuracy of CodeBERT when used independently is approximately 8.36% higher than that of the author's proposed GCN–CodeT5 model. However, higher Accuracy alone is insufficient to establish that a model has better vulnerability detection capability. For vulnerability detection, the ability to correctly identify vulnerable samples, as reflected by Recall, is particularly important. The proposed model combining GCN and CodeT5 achieves Recall of 84.23% and F1-score of 84.14%, which are higher than those of CodeBERT by 1.28% and 1.65%, respectively, indicating a better balance between detecting vulnerable samples and limiting incorrect predictions. Thus, although CodeBERT achieves higher Accuracy, the model combining GCN and CodeT5 demonstrates a more balanced performance and is better suited to the objective of source code vulnerability detection.

In the third case, only the GraphCodeBERT model is used to replace the GCN and CodeT5 components in the author's proposed model. With experimental token lengths of 128, 256, and 512 and corresponding BDC probabilities of 0.1, 0.2, and 0.3, the results shown in Table V below are obtained:

TABLE V. EXPERIMENTAL RESULTS WHEN USING ONLY THE GRAPHCODEBERT MODEL FOR SOURCE CODE FEATURE EXTRACTION

BDC	GraphCodeBERT											
	128				256				512			
	Acc	Pre	Rec	F1	Acc	Pre	Rec	F1	Acc	Pre	Rec	F1
0.1	83.78	84.16	83.78	83.68	82.14	82.76	82.14	81.98	83.63	83.81	83.63	83.57
0.2	83.78	84.16	83.78	83.68	82.14	82.76	82.14	81.98	**83.48**	**83.67**	**83.48**	**83.42**
0.3	83.78	84.16	83.78	83.68	82.14	82.76	82.14	81.98	83.48	83.7	83.48	83.41

From Table V, it can be clearly seen that the replacement model GraphCodeBERT gives poorer classification results than the model proposed in the study. Specifically, the accuracy, precision, recall, and F1-score are lower than those of the proposed model by 0.75%, 0.88%, 0.75%, and 0.72%, respectively. This result demonstrates the superiority of the combined CodeT5 and GCN model for the source code feature extraction task, proving the correctness and reasonableness of the authors' proposed model.

3) Experimental results of Scenario 3: Comparison of the SGRL model with several other approaches.

This scenario aims to evaluate and compare the SGRL model with several other studies on different experimental datasets. The two datasets used are Verum and FFmpeg+Qume, representative datasets currently widely employed in source code vulnerability detection. The Verum dataset is used in Scenarios 1 and 2 of this study, whereas FFmpeg+Qume is used in Scenario 3 to demonstrate that the SGRL model performs well not only on one dataset but also on different datasets. The experimental results for Scenario 3 are presented in Table VI.

The experimental results in Table VI show that the author's proposed method achieves substantially better results on most metrics. In this study, the author reuses the experimental results reported in study [41] to compare the proposed approach with REVEAL [41], Russell [51], VulDeePecker [52], SySeVR [55], and Devign [56]. Comparing the experimental results in Table VI with those in Table II for the Verum dataset also indicates that the proposed method performs substantially better than the other approaches. Specifically, compared with REVEAL [41], the author's proposal achieves higher Precision, Recall, and F1-score by 50.52%, 19.99%, and 39.65%, respectively; only its Accuracy is 2.71% lower than that of REVEAL. Similarly, the results of Russell [51], VulDeePecker [52], SySeVR [55], and Devign [56] are lower than those of the author's method across all metrics, ranging from a minimum difference of 66.87% in Precision to a maximum difference of 70.36% in Recall. On the FFmpeg+Qume dataset [49], the author's proposal achieves substantially better results on all metrics than the other methods, including Russell [51], VulDeePecker [52], SySeVR [55], and Devign [56], evaluated on the same FFmpeg+Qume experimental dataset. Specifically, the maximum relative improvements of the author's proposal over the other studies in Accuracy, Precision, Recall, and F1-score are 38.3%, 42.29%, 63.14%, and 55.53%, respectively. This is a very good result, indicating that the model proposed in this study is effective not only on one experimental dataset but also on multiple datasets. Its effectiveness is reflected in the experimental results, in which the proposed model achieves good results that exceed those of all other approaches on most metrics.

TABLE VI. COMPARISON RESULTS FOR THE SGRL MODEL AND OTHER APPROACHES ON THE VERUM AND FFMPEG+QUME DATASETS

Experimental Dataset	Approach	Accuracy	Precision	Recall	F1-score
Verum	**Article proposal**	**84.23**	**84.55**	**84.23**	**84.14**
	REVEAL [41]	86.94	34.03	64.24	44.49
	Russell [51]	90.98	24.63	10.91	15.24
	VulDeePecker [52]	89.05	17.68	13.87	15.7
	SySeVR [53]	84.22	24.46	40.11	30.25
	Devign [54]	88.41	34.61	26.67	29.87
FFmpeg+Qume	**Article proposal**	**90.82**	**89.65**	**91.84**	**90.73**
	REVEAL [41]	62.51	56.85	74.61	64.42
	Russell [51]	58.13	54.04	39.50	45.62
	VulDeePecker [52]	53.58	47.36	28.70	35.20
	SySeVR [53]	52.52	48.34	65.96	56.03
	Devign [54]	58.57	53.60	62.73	57.18

Fig. 6 presents the confusion matrix calculated for the proposed model with a token length of 512 and a BDC probability of 0.2.

For the FFmpeg+Qume dataset, which has a more balanced label distribution, the SGRL model demonstrates stability and strong generalization capability by correctly predicting 9,943 vulnerable samples and 12,285 normal samples. The false-

negative (FN) and false-positive (FP) counts remain symmetrically balanced across the main diagonal, demonstrating that combining graph structure (GCN) with the CodeT5 source code semantic representation model enables the system to process source code functions of substantial length and complexity effectively.

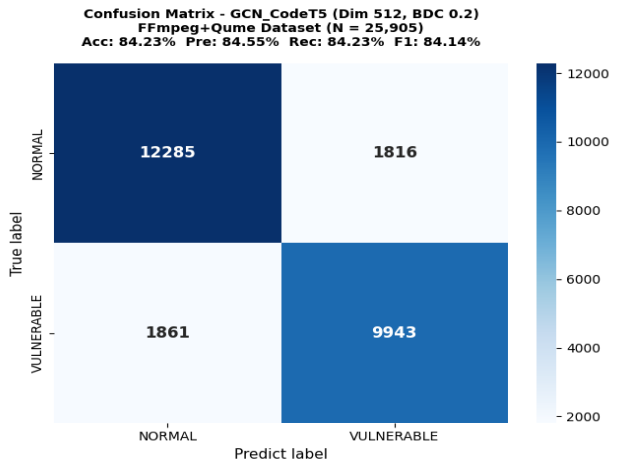

Fig. 6. Confusion matrix values of the SGRL model on the FFmpeg+Qume dataset.

V. Conclusion

Finally, from an academic perspective, the study contributes to expanding the research direction of multi-source representation learning for source code vulnerability detection by integrating a pre-trained language model with a graph neural network in a unified architecture. The research results not only affirm the complementary role between semantic representation and structural representation, but also provide an experimental basis for developing next-generation vulnerability detection models capable of simultaneously exploiting multiple sources of information from source code. This is also a premise for extending the SGRL Framework toward combining Graph Transformer, Graph Attention Network, or adaptive feature fusion mechanisms in subsequent studies. Although the proposed method has achieved promising results, the study still has several limitations. First, the method depends on the ability of Joern to analyze source code and construct the Code Property Graph (CPG). For source code with complex structures, specific syntactic characteristics, or features that are not fully supported by the tool, the quality of the generated CPG may be affected, thereby influencing the effectiveness of structural feature representation. Second, the proposed architecture integrates both Transformer and GCN branches to extract semantic and structural features, respectively, and may therefore require greater computational and memory resources than methods employing a single representation branch. These limitations should be considered when deploying the proposed method in real-world software development environments. In future research, the authors will focus on improving the ability to process complex source code and optimizing the architecture to reduce computational costs while maintaining the capability to simultaneously exploit semantic and structural information from source code. These efforts will also provide a foundation for extending the SGRL framework by integrating Graph Transformer models, Graph Attention Networks, or adaptive feature fusion mechanisms in subsequent studies.

***Abstract*—Transportability limitations can affect discrimination, probability calibration, and uncertainty estimates even when machine-learning pipelines use the same input variables. This study evaluated 5-year breast cancer survival models across METABRIC and TCGA-BRCA using age and ER, PR, and HER2 status. Logistic regression, radial-basis-function support vector machine, random forest, XGBoost, and soft voting underwent bidirectional external validation. The METABRIC soft-voting model was further assessed with source-only Platt scaling, split conformal prediction, selective prediction by singleton sets, cohort classification, and exploratory few-shot target adaptation. The principal contribution is an integrated reliability framework. METABRIC-to-TCGA ROC-AUC decreased numerically from 0.732 to 0.643, an observed difference of approximately 0.088 with a 95 percent confidence interval from minus 0.015 to 0.196. TCGA-to-METABRIC ROC-AUC decreased numerically from 0.674 to 0.586, also by approximately 0.088, with a 95 percent confidence interval from minus 0.127 to 0.282. Neither interval excluded zero. Source Platt scaling improved the observed internal Brier score and expected calibration error but produced worse observed values for both metrics externally. TCGA empirical conformal coverage was 81.8 percent versus nominal 90 percent. Exploratory target recalibration improved mean locked-test Brier score and expected calibration error at larger target sample sizes, whereas updating only the conformal threshold did not restore nominal mean coverage. These findings support separate evaluation of ranking, probability accuracy, and uncertainty under cohort shift and do not establish model superiority, clinical usefulness, or deployment readiness.**

Keywords*—Machine learning; transportability; external validation; probability calibration; conformal prediction; selective prediction; cohort shift; few-shot recalibration; survival prediction

I. Introduction

Five-year overall survival is a clinically interpretable endpoint, and breast cancer contributes substantially to global cancer incidence [1]. Prognosis and the data used to estimate it vary across patient populations and data-generating settings. Machine-learning models can combine clinical predictors through linear, kernel-based, tree-based, and ensemble relationships, yet apparent performance within a development cohort does not establish performance in a distinct population [2]. Differences in case mix, variable definitions, missingness, care pathways, and follow-up can alter discrimination and probability calibration even when the same predictor names are available.

External validation is therefore central to evaluating model transportability [3,4]. Discrimination measures whether a model ranks patients with different outcomes; calibration measures agreement between predicted probabilities and observed outcome frequencies [4,5]. A transported model may retain ranking but yield inaccurate probabilities. A calibration map fitted in the source cohort may not improve calibration in the target cohort.

Uncertainty methods introduce a second transportability question. Split conformal classification can produce patient-specific prediction sets with finite-sample marginal coverage under exchangeability [6]. That guarantee does not automatically extend to a target cohort under distribution shift [7]. Empirical coverage and abstention behavior must consequently be evaluated in the target cohort rather than assumed. Limited labeled target data may permit probability recalibration or re-estimation of a conformal threshold, but small adaptation samples can introduce instability.

These issues were investigated in two clinical breast cancer cohorts, METABRIC and the TCGA-BRCA publication cohort. The study had four objectives: quantify observed internal-to-external performance changes in both transport directions; assess whether source-only Platt scaling transported from METABRIC to TCGA; evaluate source split-conformal coverage and conformal abstention internally and externally; and explore whether few-shot target adaptation improved probability calibration or restored nominal conformal coverage on a locked TCGA test set. The study design and protected information boundaries are summarized in Fig. 1 in Section III.

The principal contribution of this work is an integrated cross-cohort machine-learning reliability framework. It examines discrimination transportability, probability calibration, conformal coverage, selective prediction, cohort shift, and limited-label target adaptation under protected external evaluation.

Specifically, the study contributes: 1) bidirectional METABRIC↔TCGA external validation of five machine-learning models; 2) joint assessment of discrimination, probability calibration, and conformal uncertainty rather than reliance on accuracy or ROC-AUC alone; 3) evaluation of

*Corresponding author.

whether source-derived Platt calibration and empirical conformal coverage remain reliable after cohort transport; and 4) exploratory few-shot target adaptation with a permanently locked target test, separating probability recalibration from conformal-threshold adaptation.

The remainder of this study is organized as follows. Section II reviews related work on external validation, calibration, dataset shift, and conformal prediction. Section III describes the cohorts, endpoint, protected modeling workflow, calibration and conformal procedures, and statistical analysis. Section IV presents cross-cohort performance, calibration, uncertainty, domain-shift, and exploratory few-shot results. Section V discusses the findings and outlines future work; Section VI summarizes limitations, and Section VII concludes the study.

II. Related Work

METABRIC and TCGA-BRCA have both supported research on breast cancer biology and outcomes, but they differ in study design, composition, and available clinical fields [8,9]. Similar variable names cannot be assumed to have identical meanings across the two studies. A systematic review of 31 machine-learning studies of 5-year breast-cancer survival found that all used internal validation, but only one used external validation and only one assessed calibration [2]. Later work externally evaluated 87 breast-cancer prediction models [10] and compared statistical and machine-learning approaches through internal-external validation [11]. These studies support assessing discrimination and calibration in new populations. Related image-based work combined CLAHE-enhanced mammograms with EfficientNetV2S for breast-cancer classification [12]. A systematic review also examined deep-learning methods for breast-cancer classification [13]. These image-based diagnostic tasks differ from transporting clinical survival probabilities across cohorts.

Clinical prediction guidance recommends protected separation of development, tuning, calibration, and final evaluation, together with uncertainty-aware reporting [3,4,14]. Dataset shift can produce performance changes after deployment. Recent clinical work studied stable prediction under temporal electronic-health-record shift [15]. Cohort-membership classifiers provide a complementary label-free measure of multivariable shift [16]. Covariate differences alone do not establish that transported probabilities or uncertainty sets remain reliable.

Calibration can change even when ranking is retained [5]. Platt scaling uses a parsimonious logistic score transformation [17]. Model-updating research includes slope-and-intercept recalibration with attention to sample size [18], broader guidance on recalibration and revision [19], target-time correction of calibration shift [20], and dynamic updating under changing clinical environments [21]. This literature supports evaluating limited-label updating. It does not justify using the target test set to choose an updating method or sample size.

Conformal prediction provides set-valued uncertainty under exchangeability, and weighted approaches address specified covariate-shift settings [6,7]. More recent work extends conformal inference beyond exchangeability [22] and develops doubly robust calibration of prediction sets under covariate shift [23]. Selective-prediction methods separately formalize abstention or rejection [24,25]. The present study evaluates conventional source split-conformal sets and singleton-based selective prediction empirically after transport; it does not claim the guarantees of these shift-robust extensions.

Existing studies address different parts of this reliability problem. Breast-cancer external-validation studies commonly assess discrimination and calibration, whereas methodological work examines shift, conformal prediction, selective prediction, or model updating [2,10,11,19,22,23,25]. This study evaluates those components in one protected patient-level cross-cohort workflow.

III. Materials and Methods

A. Study Design and Cohorts

This was a retrospective secondary analysis of clinical data from METABRIC (brca_metabric) and TCGA-BRCA (brca_tcga_pub). Only patient-level and sample-level clinical data obtained through the official cBioPortal REST API were used; no mutation, expression, copy-number, imaging, or complete study-archive data were included. The unit of analysis was the patient. Stable patient identifiers were required and checked for duplication before modeling.

Each cohort served once as the source and once as the external cohort. The bidirectional baseline analyses transported METABRIC models to all eligible TCGA patients and TCGA models to all eligible METABRIC patients. Source calibration, split-conformal, and domain-shift analyses used the fixed METABRIC soft-voting model with TCGA as the external cohort. The few-shot analysis was exploratory and post hoc. Fig. 1 shows the protected workflows. Panel A separates source training, disjoint probability and conformal calibration, and evaluation without refitting; it also shows the complementary TCGA-to-METABRIC baseline direction. Panel B shows separate target probability and conformal-threshold branches, each evaluated only on the locked TCGA test.

B. Five-Year Overall-Survival Outcome

Overall survival status was harmonized from OS_STATUS, with 0: LIVING mapped to living and 1: DECEASED mapped to deceased. Overall survival time was parsed from nonnegative OS_MONTHS. The binary endpoint used a 60-month horizon. Death on or before 60 months was assigned y_5yr=0; documented survival beyond 60 months was assigned y_5yr=1, irrespective of a later death or censoring event. Patients recorded as living or censored on or before 60 months were excluded because their 5-year outcome was not observed. Patients with missing, invalid, conflicting, or otherwise unsupported required outcome fields were also excluded. The resulting class proportions describe the outcome-eligible analytic samples and should not be interpreted as population survival estimates.

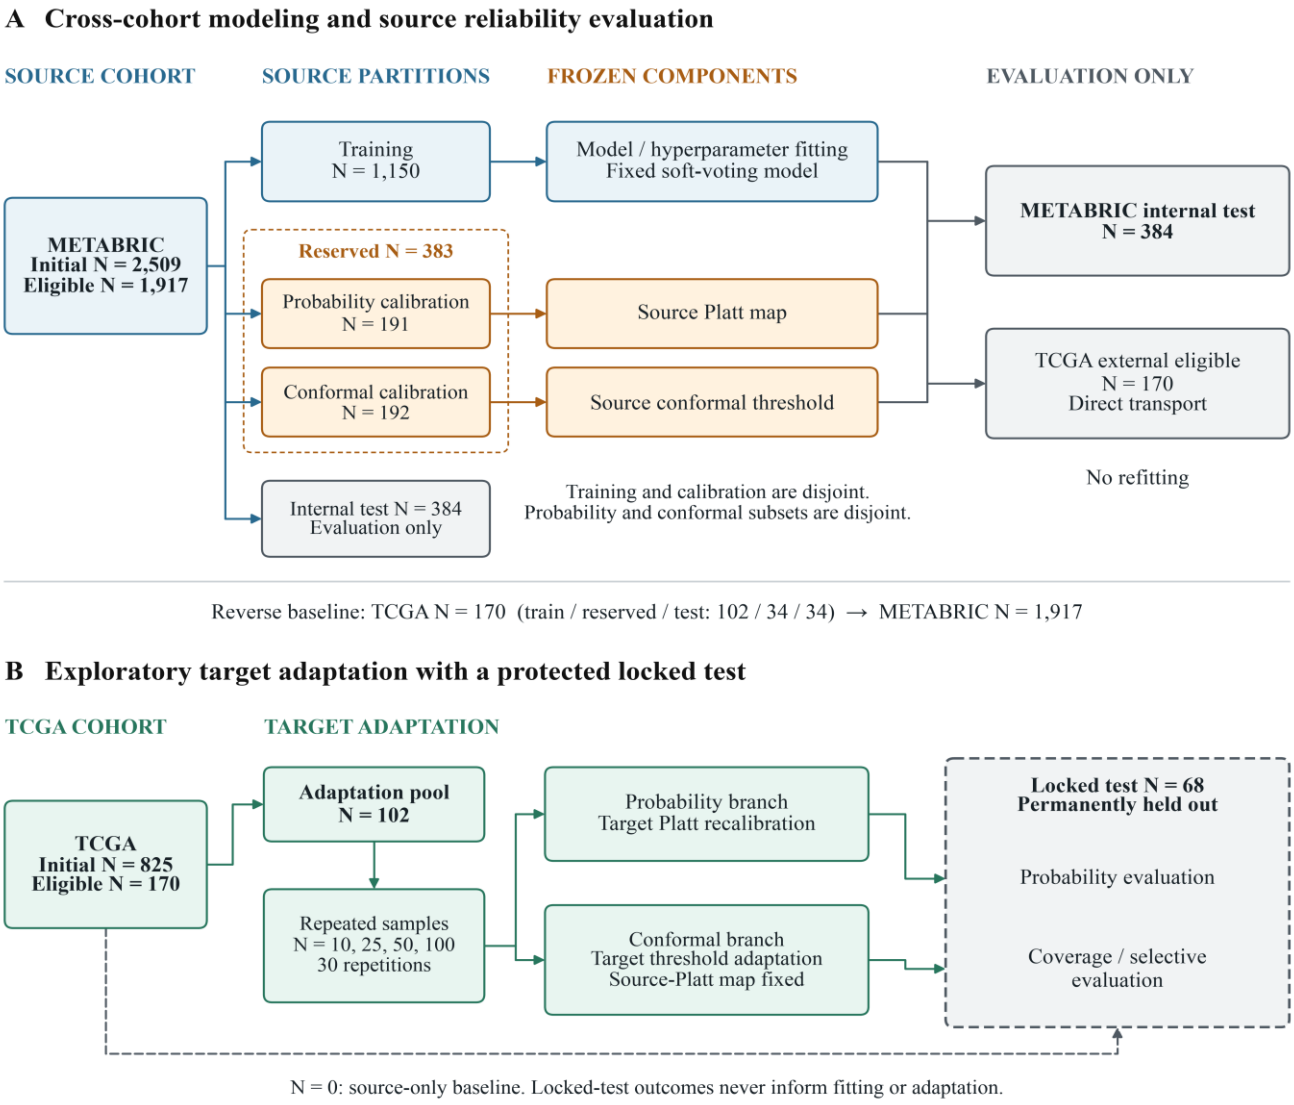

Fig. 1. Study design and protected information boundaries. (A) Bidirectional cross-cohort validation and detailed METABRIC-to-TCGA source calibration and conformal evaluation. (B) Exploratory few-shot target adaptation used a 102-patient TCGA adaptation pool; the 68-patient locked test was reserved for evaluation only.

C. Predictor Harmonization

Candidate shared clinical variables were audited before mapping. Age was parsed in years from AGE_AT_DIAGNOSIS in METABRIC and AGE in TCGA; nonnumeric values or values outside 0–120 years were treated as missing. ER_STATUS, PR_STATUS, and HER2_STATUS were mapped only when the observed value was exactly Positive or Negative. Unknown, equivocal, indeterminate, unavailable, unsupported, conflicting, or absent values were treated as missing.

Tumor stage was not included in primary modeling. METABRIC numeric stages 1–4 could be mapped to I–IV, but TCGA TUMOR_STAGE values represented T categories rather than supported overall stages. Consequently, harmonized stage was missing for all 170 outcome-eligible TCGA patients. The final predictor set was age at diagnosis, estrogen-receptor status, progesterone-receptor status, and HER2 status.

D. Source Partitions and Preprocessing

Random seed 42 was used for source modeling. Within each eligible source cohort, a stratified split allocated approximately 60% to training, 20% to a reserved calibration partition, and 20% to an untouched internal test. METABRIC contributed 1,150 training, 383 reserved calibration, and 384 internal-test patients. TCGA contributed 102, 34, and 34 patients, respectively. Hyperparameter selection used only the training split; the internal test and all external patients were not used for fitting or selection.

Preprocessing was encapsulated in the model pipeline. Age underwent median imputation and standardization. Receptor variables underwent most-frequent imputation followed by one-hot encoding with unknown categories ignored at transformation. Every preprocessing operation was fitted within the applicable training data, including separately within each cross-validation fold, and then applied without refitting to calibration and evaluation patients.

E. Models and Hyperparameter Selection

Five model families were evaluated: logistic regression, radial-basis-function support vector machine with probability output, random forest, XGBoost, and an equal-weight soft-voting ensemble of the four component models. Component hyperparameters were selected by five-fold stratified cross-validation within the source training split, using ROC-AUC as the optimization metric. The small grids varied logistic-regression regularization strength and class weighting; support-vector regularization, kernel scale, and class weighting; random-forest tree count, maximum depth, and minimum leaf size; and XGBoost tree count, depth, and learning rate. The soft-voting model averaged the four fitted component probabilities with weights 1:1:1:1. All stochastic estimators used seed 42.

F. Reproducibility Details

Exact five-fold source-training grids were as follows: logistic regression C∈{0.1, 1.0, 10.0} and class_weight∈{None, balanced}; RBF-SVM C∈{0.5, 1.0, 2.0}, gamma∈{scale, 0.1}, and class_weight∈{None, balanced}; random forest n_estimators∈{100, 200}, max_depth∈{None, 5}, and min_samples_leaf∈{1, 5}; and XGBoost n_estimators∈{100, 200}, max_depth∈{2, 3}, and learning_rate∈{0.05, 0.1}. XGBoost subsample and colsample_bytree were fixed at 0.8. Selection used source-training ROC-AUC only.

Selected METABRIC-source settings were logistic regression C=1.0 with balanced weights; RBF-SVM C=1.0, gamma=0.1, balanced; random forest 100 trees, depth 5, minimum leaf 5; and XGBoost 100 trees, depth 2, learning rate 0.05. Selected TCGA-source settings were logistic regression C=10.0, balanced; RBF-SVM C=2.0, gamma=scale, balanced; random forest 200 trees, depth 5, minimum leaf 5; and XGBoost 100 trees, depth 2, learning rate 0.1. Each soft-voting model used the selected components with weights 1:1:1:1.

The verified environment was Python 3.11.9 with numpy 2.4.6, pandas 3.0.5, scipy 1.17.1, scikit-learn 1.9.0, xgboost 3.2.0, matplotlib 3.11.1, statsmodels 0.14.6, joblib 1.5.3, and requests 2.34.2. Age parsing, receptor mappings, training-only imputation, one-hot encoding, and scaling are specified above and implemented within fitted pipelines. The source Platt map recorded slope 0.907921 and intercept 0.470539; these are transformation coefficients, not external calibration-slope or calibration-intercept performance measures.

Clinical records for brca_metabric and brca_tcga_pub were retrieved on 9 August 2026 (UTC) from https://www.cbioportal.org/api/ using study-specific clinical-attributes and clinical-data endpoints; no separate server API-version string was recorded. The reproducibility archive includes deterministic extraction and harmonization logic, aggregate results, and SHA-256 patient-manifest hashes rather than patient identifiers in the paper. The local repository had no recorded commit and no verified paper-specific public URL or DOI at camera-ready preparation.

G. Internal and External Validation

Each fitted source model was evaluated on its source internal test and directly on all outcome-eligible patients in the other cohort. No target outcome was used for preprocessing, hyperparameter selection, calibration, threshold choice, or model selection. Metrics were ROC-AUC, precision-recall AUC, accuracy, balanced accuracy, sensitivity, specificity, F1 score, Matthews correlation coefficient, and Brier score. The positive class was y_5yr=1. The fixed 0.5 probability threshold was used as a descriptive operating point and was not selected or optimized for a clinical decision context. After inspection of internal descriptive performance, the METABRIC soft-voting model—whose observed internal-test ROC-AUC was highest among the five METABRIC-source models—was carried forward for the detailed calibration, conformal, domain-shift, and few-shot analyses. This was a descriptive, post hoc model-specific choice; these secondary analyses are not used to support a comparative superiority claim.

H. Probability Calibration

Calibration analysis used the reproduced METABRIC soft-voting model and the identical source partitions and component hyperparameters. The 383-patient METABRIC reserved calibration partition was divided, stratified with seed 42, into 191 patients for probability calibration and 192 for conformal calibration. A logistic Platt map was fitted on the logit of the uncalibrated soft-voting probability using only the 191-patient probability-calibration subset. Probabilities were clipped to 10^-6 and 1−10^-6 only for logit transformation. Uncalibrated and Platt-scaled predictions were evaluated on the METABRIC internal test and all 170 eligible TCGA patients using ROC-AUC, Brier score, ten-bin expected calibration error (ECE), and log loss. Reliability plots display observed outcome frequency against mean predicted probability with bin counts (Fig. 3).

I. Split Conformal Prediction and Abstention

The Platt-scaled model was fixed before conformal calibration. For each of the 192 conformal-calibration patients, the nonconformity score was one minus the probability assigned to the observed class. At alpha=0.10, the finite-sample corrected empirical quantile used rank ceil((n+1)(1-alpha)). A candidate class was included when its nonconformity score did not exceed the resulting threshold. The same source-derived threshold was applied to the METABRIC internal test and all eligible TCGA patients.

Outcomes were empirical coverage, mean prediction-set size, singleton rate, defer rate, and accuracy among singleton sets. Selective prediction was operationalized through conformal singleton status: singleton sets yielded a class prediction, whereas empty or two-class sets were deferred. Because target exchangeability was not assumed, TCGA coverage was interpreted as empirical external coverage rather than a guaranteed quantity [6,7].

J. Domain-Shift Analysis

A separate cohort-membership classifier was used to distinguish eligible METABRIC from eligible TCGA patients using only age and ER, PR, and HER2 status. The classifier was a class-balanced logistic-regression pipeline with the same training-fitted preprocessing rules. Five-fold stratified cross-validation with seed 42 produced ROC-AUC and balanced accuracy for cohort discrimination. No survival outcome was used. Descriptive comparisons included age, receptor positivity among nonmissing observations, and predictor missingness.

K. Exploratory Few-Shot Target Adaptation

The 170 eligible TCGA patients were split with stratification and seed 2026 into an adaptation pool of 102 patients and a permanently locked test of 68 patients. The locked test was not used for fitting, calibration, threshold selection, model selection, or choice of target sample size. It contained 22 y_5yr=0 and 46 y_5yr=1 patients.

Target sample sizes were N=0, 10, 25, 50, and 100. N=0 used the source Platt map and source conformal threshold. For each N greater than zero, a stratified sample was drawn from the adaptation pool in 30 repetitions using fixed seeds. Probability adaptation fitted a target Platt map, including slope and intercept, on the sampled patients' fixed METABRIC model scores and evaluated the resulting probabilities on the unchanged locked test. The cancer classifier and its preprocessing were never retrained.

Target conformal adaptation was evaluated as a parallel branch. The source model and source Platt probability function remained fixed, and only the conformal threshold was re-estimated from the N labeled target patients. This target-derived threshold was then evaluated on the same locked test using the fixed source-Platt probabilities. Thus, target labels influenced the probability-recalibration parameters in one branch or the conformal threshold in the other, but never the cancer predictor or locked-test evaluation choices.

L. Protocol Deviations and Exploratory Analyses

The original protocol intent was retained as the confirmatory plan: target sample sizes N = 0, 25, 50, 100, 200 and intercept-only target recalibration. The executed few-shot analysis differed by using N = 0, 10, 25, 50, 100 and fitting both a slope and an intercept through Platt recalibration. The N = 10 condition and fitted slope were not in the initial plan, and N = 200 was not feasible because the realized adaptation pool contained 102 patients. The executed few-shot analysis is therefore designated exploratory and post hoc. Its results are hypothesis-generating and are not treated as confirmatory evidence for the original specification.

The information boundary was nevertheless preserved. The 68-patient locked test remained disjoint from the 102-patient adaptation pool and untouched by model fitting, probability recalibration, conformal-threshold estimation, threshold or sample-size selection, and stopping decisions. The fixed locked test was used only for evaluation after those choices had been set, and the cancer classifier was never retrained.

Probability recalibration and conformal adaptation were separate exploratory branches. Target Platt recalibration evaluated probability calibration by fitting slope and intercept on the sampled target patients. Conformal target adaptation did not use the target-Platt probabilities: it updated only the nonconformity threshold using the sampled target labels while keeping the cancer model and source-Platt probabilities fixed.

M. Statistical Analysis

Point estimates and 95% confidence intervals for ROC-AUC, precision-recall AUC, Brier score, sensitivity, and specificity were computed using 2,000 patient-level nonparametric bootstrap replicates and percentile limits [3,4]. The same resampled patient indices were used across models evaluated on a common cohort, permitting paired comparisons. Internal-minus-external ROC-AUC differences and external-minus-internal Brier differences were calculated from bootstrap distributions. Pairwise model comparisons were performed for ROC-AUC and Brier score within each evaluation setting; two-sided bootstrap P values were adjusted within each family using Holm's method [26]. Conformal coverage received Wilson 95% confidence intervals.

For few-shot adaptation, each N greater than zero was summarized across 30 target-sampling repetitions by the mean, standard deviation, and 2.5th and 97.5th percentiles. These percentiles quantify variation due to the sampled adaptation patients while holding the 68-patient locked test fixed; they are not patient-level confidence intervals for a new target population. Analyses used Python 3.11 and the fixed software environment recorded in the project.

IV. Results

A. Cohorts and Outcome Eligibility

METABRIC contained 2,509 patients, of whom 1,917 had an observable binary 5-year outcome; 427 (22.27%) were classified as death by 60 months and 1,490 (77.73%) as known survival beyond 60 months. Of 592 excluded patients, 64 were alive or censored by 60 months and 528 lacked valid overall-survival months. TCGA contained 825 patients, of whom 170 were outcome eligible; 55 (32.35%) were classified as death by 60 months and 115 (67.65%) as known survival beyond 60 months. Of 655 exclusions, 648 were alive or censored by 60 months, and seven lacked valid overall-survival months.

Among eligible patients, mean age was 61.19 years in METABRIC and 57.22 years in TCGA. ER-positive proportions among nonmissing observations were 76.21% and 70.55%, PR-positive proportions were 52.97% and 60.74%, and HER2-positive proportions were 12.32% and 13.10%, respectively. TCGA predictor missingness was 4.12% for ER, 4.12% for PR, and 14.71% for HER2, compared with 0%, 0.05%, and 0.05% in METABRIC. Cohort characteristics are presented in Table I.

TABLE I. Cohort Characteristics for the Outcome-Eligible Analytic Samples. Receptor Percentages use Nonmissing Denominators

Cohort	Initial N	Eligible N	Death by 60 months	Survival beyond 60 months	Age, mean (SD)	ER positive	PR positive	HER2 positive	Missing ER / PR / HER2
METABRIC	2,509	1,917	427 (22.27%)	1,490 (77.73%)	61.19 (12.94)	76.21%	52.97%	12.32%	0.00% / 0.05% / 0.05%
TCGA	825	170	55 (32.35%)	115 (67.65%)	57.22 (14.42)	70.55%	60.74%	13.10%	4.12% / 4.12% / 14.71%

B. Bidirectional Internal and External Performance

For METABRIC-source models, the soft-voting ensemble had the highest observed internal ROC-AUC: 0.732 (95% CI, 0.672–0.786) on 384 internal-test patients. Its ROC-AUC was 0.643 (95% CI, 0.557–0.728) on all 170 eligible TCGA patients (Table II; Fig. 2). The observed internal-to-external numerical decrease was approximately 0.088 (95% CI, -0.015 to 0.196). Because this interval included zero, the decrease was not statistically significant. Brier score increased from 0.160 (95% CI, 0.142–0.177) internally to 0.214 (95% CI, 0.182–0.247) externally, an external-minus-internal difference of 0.054 (95% CI, 0.020–0.090). Precision-recall AUC was 0.903 internally and 0.768 externally.

For TCGA-source models, the RBF support vector machine had the highest observed internal ROC-AUC: 0.674 (95% CI, 0.460–0.861) on 34 patients. Applied to all 1,917 eligible METABRIC patients, its ROC-AUC was 0.586 (95% CI, 0.554–0.615). The observed internal-to-external numerical decrease was also approximately 0.088 (95% CI, -0.127 to 0.282), and this interval likewise included zero. Its Brier score was 0.206 (95% CI, 0.155–0.263) internally and 0.183 (95% CI, 0.177–0.190) externally, an external-minus-internal difference of -0.023 (95% CI, -0.080 to 0.028). The TCGA-source internal estimate is substantially less precise because the source internal test contains only 34 patients; the two transport directions therefore should not be interpreted as providing symmetric statistical evidence.

Threshold-based performance was uneven. The METABRIC-source soft-voting model had sensitivity 0.956 and specificity 0.174 internally, and sensitivity 0.930 and specificity 0.109 in TCGA. Several RBF support-vector evaluations assigned every patient to the positive class at the fixed descriptive 0.5 operating point, yielding sensitivity 1.000 and specificity 0.000; the zero specificity reflects this fixed operating point and is not a recommended clinical threshold. Complete metrics and bootstrap intervals for all five models are provided in Table II. Holm-adjusted pairwise model-comparison results are retained in the verified statistical output, but the approximately 0.088 cross-cohort numerical decreases above are interpreted from their confidence intervals and are not labeled significant.

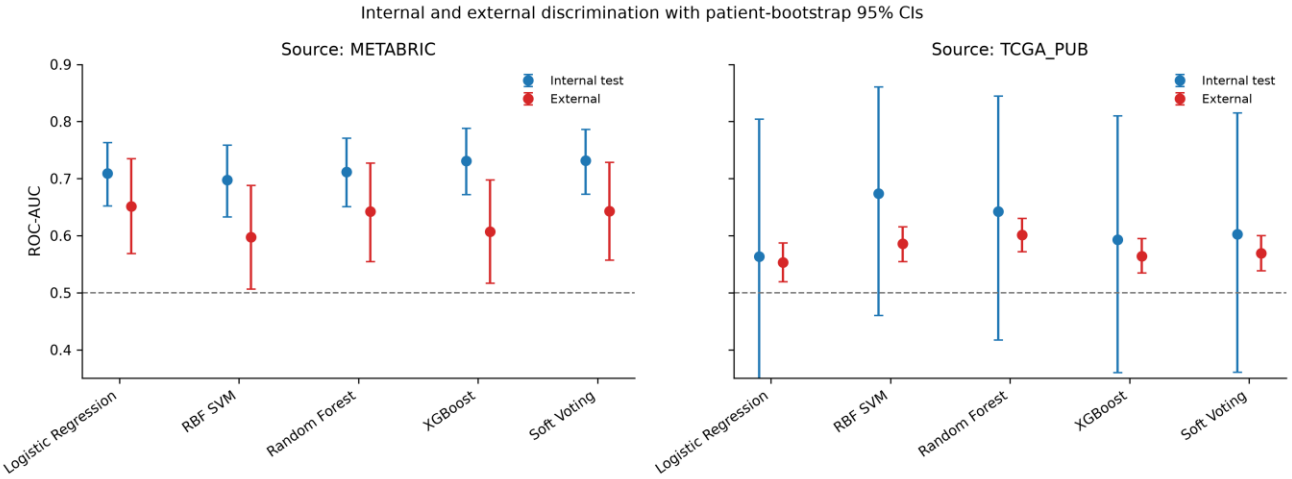

Fig. 2. Internal and external ROC-AUC for both transport directions with 95 percent bootstrap confidence intervals.

C. Calibration and Conformal Transport

On the METABRIC internal test, source Platt scaling preserved ROC-AUC at 0.732 while changing Brier score from 0.160 to 0.157, ECE from 0.066 to 0.044, and log loss from 0.494 to 0.485. In TCGA, ROC-AUC remained 0.643, but source-only Platt scaling worsened the Brier score from 0.214 to 0.222, ECE from 0.078 to 0.104, and log loss from 0.616 to 0.641. Fig. 3 shows the corresponding reliability plots, and Table III reports the calibration and conformal metrics. Thus, the source calibration map showed a small favorable internal change but did not transport as an improvement in external calibration.

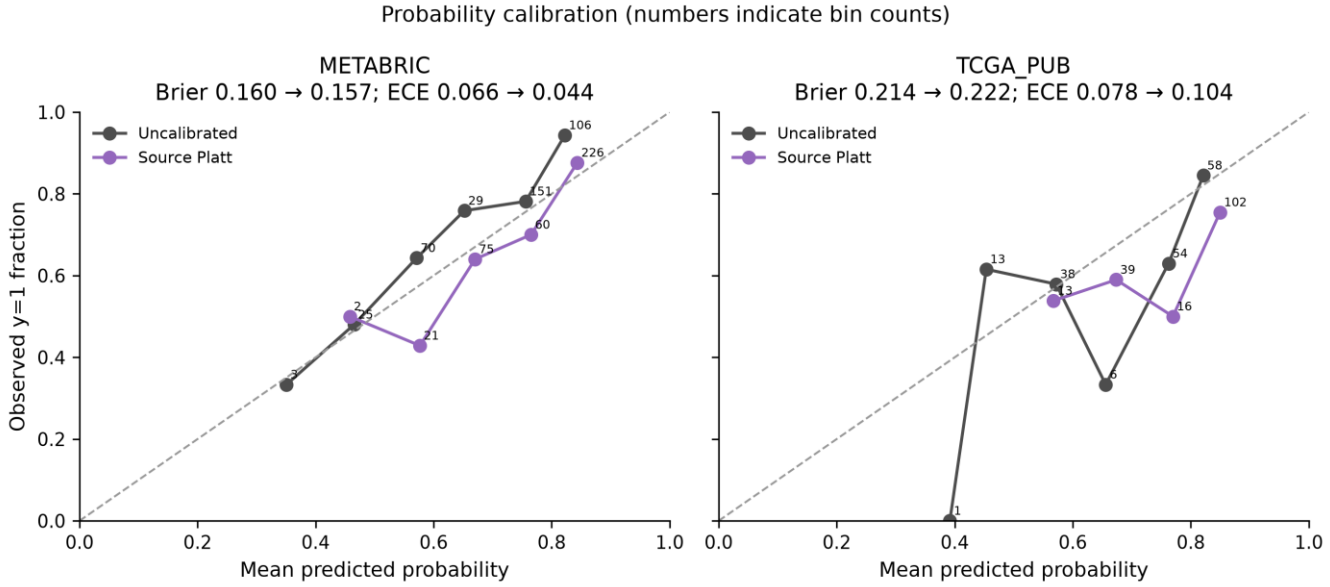

Fig. 3. Calibration behavior of the fixed METABRIC soft-voting model before and after source Platt scaling.

At nominal 90% coverage, empirical conformal coverage was 0.891 (Wilson 95% CI, 0.855–0.918) on the METABRIC internal test and 0.818 (Wilson 95% CI, 0.753–0.868) in TCGA (Fig. 4). The external interval did not include 0.900. Mean prediction-set size was 1.302 internally and 1.329 externally. Singleton and defer rates were 0.698 and 0.302 internally, compared with 0.671 and 0.329 externally. Accuracy among singleton predictions was 0.843 internally and 0.728 externally. These results show external undercoverage of the source-derived conformal sets.

TABLE III. SOURCE CALIBRATION AND SPLIT-CONFORMAL TRANSPORT AT ALPHA 0.10. ECE USED TEN EQUAL-WIDTH BINS. TCGA COVERAGE IS EMPIRICAL EXTERNAL COVERAGE

Evaluation	N	Uncalibrated AUC	Uncalibrated Brier / ECE / log loss	Platt Brier / ECE / log loss	Coverage [Wilson 95% CI]	Mean set size	Singleton	Defer	Singleton accuracy
METABRIC internal	384	0.732	0.160 / 0.066 / 0.494	0.157 / 0.044 / 0.485	0.891 [0.855–0.918]	1.302	0.698	0.302	0.843
TCGA external	170	0.643	0.214 / 0.078 / 0.616	0.222 / 0.104 / 0.641	0.818 [0.753–0.868]	1.329	0.671	0.329	0.728

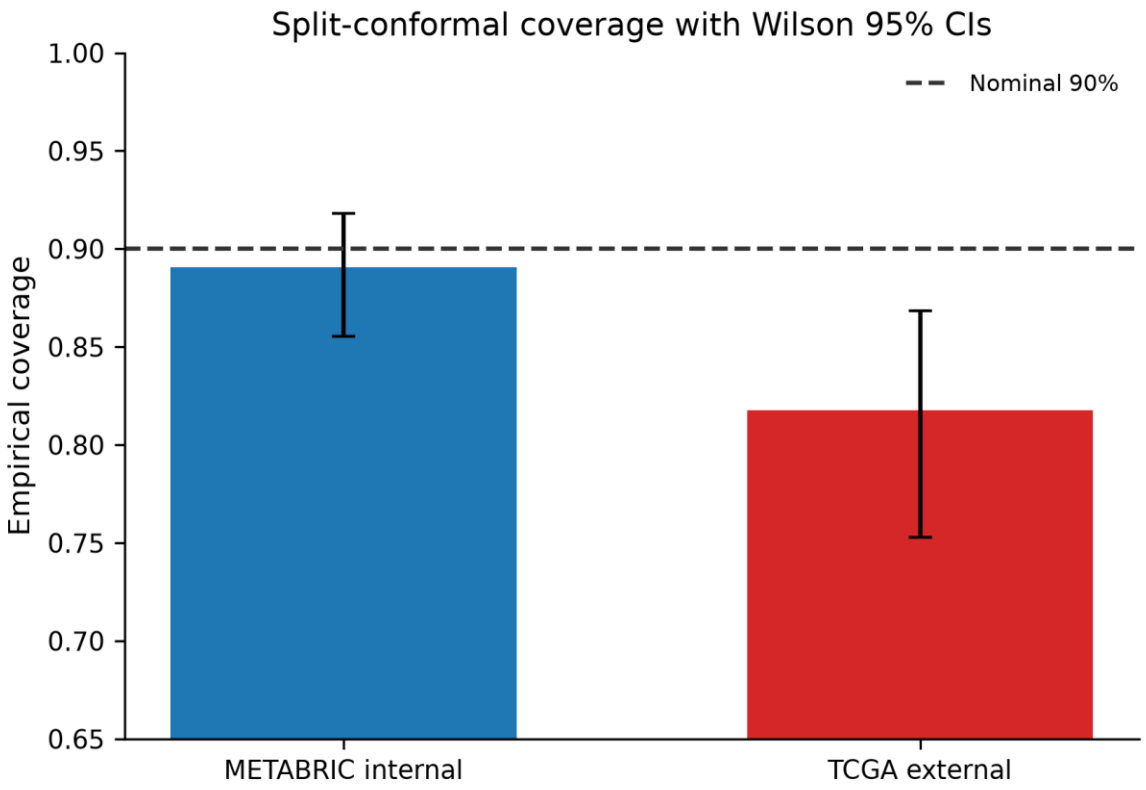

Fig. 4. Internal and external empirical split-conformal coverage relative to the nominal 90 percent level.

D. Domain Shift

Eligible TCGA patients were younger on average than METABRIC patients by 3.97 years, with a standardized mean difference of -0.290. Receptor prevalence and missingness also differed, most notably for HER2 missingness. The cohort-membership classifier achieved mean five-fold ROC-AUC 0.604 (SD, 0.049) and balanced accuracy 0.574 (SD, 0.047). These label-free results indicate measurable, although incomplete, separability using the four harmonized predictors and their missingness patterns.

E. Exploratory Few-Shot Target Adaptation

The TCGA adaptation pool contained 102 patients (33 y_5yr=0, 69 y_5yr=1), and the locked test contained 68 patients (22 and 46, respectively). Table IV and Fig. 5 summarize repeated target adaptation. With N=0, the locked-test Brier score was 0.226, and ECE was 0.128. At N=10, mean Brier score was 0.254 (SD, 0.059) and mean ECE was 0.162 (SD, 0.109), showing instability at the smallest target sample. Mean Brier score and ECE were 0.219 and 0.066 at N=25, 0.214 and 0.047 at N=50, and 0.213 and 0.036 at N=100. Relative to N=0, larger target samples therefore improved both locked-test Brier score and ECE without retraining the cancer classifier. Singleton accuracy at N=10 was not summarized because three of the 30 repetitions produced no singleton predictions, making per-repetition singleton accuracy undefined and causing the frozen all-repetition aggregation to return NA.

Target conformal adaptation did not restore mean nominal coverage. Mean coverage was 0.809 at N=0, 0.882 at N=10, 0.886 at N=25, 0.866 at N=50, and 0.868 at N=100. The highest mean was 0.886 at N=25, below 0.900. Mean defer rates were 0.294, 0.543, 0.554, 0.469, and 0.456 across the same N values. Fig. 5 displays Brier score, ECE, and conformal coverage with 2.5th–97.5th percentiles and the nominal 90% reference line.

TABLE IV. EXPLORATORY FEW-SHOT TARGET ADAPTATION ON THE FIXED 68-PATIENT TCGA LOCKED TEST. VARIATION IS ACROSS TARGET SAMPLES, NOT PATIENT-BOOTSTRAP CONFIDENCE INTERVALS

Target N	Repetitions	Brier mean (SD)	ECE mean (SD)	Log loss mean (SD)	Coverage mean (SD)	Mean set size	Defer mean (SD)	Singleton accuracy mean (SD)
0	1	0.226 (0.000)	0.128 (0.000)	0.653 (0.000)	0.809 (0.000)	1.294	0.294 (0.000)	0.729 (0.000)
10	30	0.254 (0.059)	0.162 (0.109)	1.426 (2.632)	0.882 (0.065)	1.543	0.543 (0.240)	NA
25	30	0.219 (0.009)	0.066 (0.047)	0.633 (0.025)	0.886 (0.044)	1.554	0.554 (0.172)	0.740 (0.029)
50	30	0.214 (0.001)	0.047 (0.020)	0.618 (0.003)	0.866 (0.013)	1.469	0.469 (0.048)	0.747 (0.012)
100	30	0.213 (0.000)	0.036 (0.009)	0.615 (0.000)	0.868 (0.000)	1.456	0.456 (0.000)	0.757 (0.000)

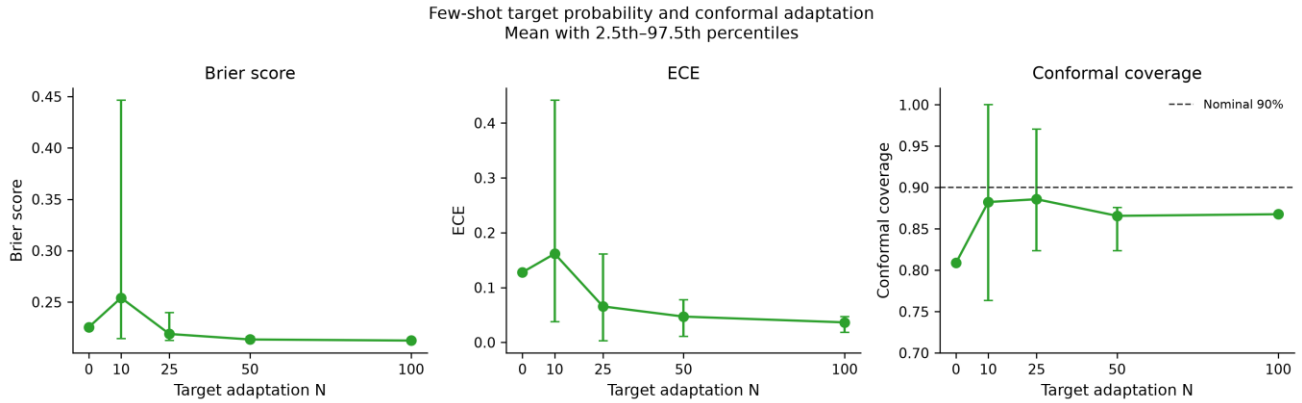

Fig. 5. Exploratory few-shot target recalibration and conformal threshold adaptation on the fixed TCGA locked test.

V. Discussion

The main finding was an observed numerical decrease in discrimination in both transport directions. At the reported precision, the METABRIC soft-voting model and the highest-observed-AUC TCGA internal model each showed an internal-to-external ROC-AUC difference of approximately 0.088. This numerical similarity is descriptive: both 95% confidence intervals included zero, so neither decrease was statistically established. The TCGA-source internal estimate is substantially less precise because its internal test contained only 34 patients; the two directions therefore provide complementary evidence about directionality but not symmetric statistical evidence. The soft-voting model was carried forward for detailed uncertainty analysis only after inspection of internal descriptive performance. Accordingly, those model-specific analyses are secondary and do not support a claim of prospectively selected superiority.

Probability calibration exposed a different aspect of transportability. Source Platt scaling improved the observed METABRIC internal Brier score, ECE, and log loss, but the same fixed map produced worse observed values for all three metrics in TCGA. ROC-AUC was unchanged because the fitted transformation preserved score ordering. Discrimination and calibration therefore answered different questions. These metric changes show that the source map did not transport as an observed improvement in TCGA; the ten-bin ECE alone is not treated as proof of general calibration failure. Source-only recalibration should be evaluated externally as part of the transported prediction system. It cannot be assumed to be universally corrective.

The conformal analysis showed a parallel limitation of source-derived uncertainty after transport. Empirical coverage was 89.1% on the METABRIC internal test, close to the nominal 90%, but 81.8% in TCGA. The TCGA Wilson interval ended at 86.8%, and external evaluation also showed a higher defer rate and lower singleton accuracy. Split-conformal validity depends on an exchangeability relationship between calibration and evaluation observations; that relationship was not established across these cohorts. The result is therefore external empirical undercoverage, not a failure of conformal theory or a contradiction of the source guarantee.

The label-free domain analysis provided context without identifying a cause. A cohort-classifier ROC-AUC of 0.604 showed that METABRIC and TCGA were partly distinguishable using the four predictors and their missingness patterns. TCGA patients were younger on average, receptor distributions differed, and HER2 missingness was higher. These findings are compatible with covariate shift, but they do not attribute the performance changes to any single variable or exclude unmeasured differences in selection, follow-up, or care. Because the shift analysis was not used to select features or models, it informs interpretation rather than comparative model ranking.

The exploratory, post hoc few-shot analysis separated probability recalibration from conformal threshold adaptation. Target Platt recalibration improved mean locked-test Brier score and ECE at N=25, 50, and 100 relative to N=0, with the lowest means at N=100. N=10 was worse and highly variable. Estimating both a calibration slope and intercept from very limited labels was unstable. These probability results suggest that labeled target data can correct aspects of the score-to-risk relationship, but they remain conditional on one 68-patient locked test and do not establish a generally effective adaptation sample size.

The conformal branch answered a narrower and separate question. It kept the cancer model and source-Platt probabilities fixed and updated only the conformity threshold using target adaptation patients. This simple threshold update did not restore mean 90% coverage at any evaluated N; the highest mean coverage was 88.6% at N=25, and coverage was 86.8% at N=100. The lack of monotonic recovery indicates that a target-derived threshold alone was insufficient in this small experiment. It does not compare alternative conformal methods and cannot support a superiority claim about any uncertainty procedure.

These results concern the transportability of the complete prediction workflow. Internal discrimination did not determine external discrimination, and internal calibration improvement did not imply external calibration improvement. Near-nominal internal conformal coverage also did not imply target coverage. Cross-cohort evaluation should keep target data protected and label post hoc adaptation explicitly. Ranking, probability accuracy, and set coverage should be reported separately. The

present findings do not establish clinical usefulness or deployment readiness.

A. Future Work

Future external-validation studies should use larger cohorts and clinically prespecified operating thresholds, with threshold uncertainty and decision-curve/net-benefit analysis. Calibration assessment should add calibration intercept and slope, flexible calibration curves with uncertainty bands, and a prevalence-only Brier reference. Richer harmonization should examine overall stage where semantically defensible, principled treatment of cohort-specific HER2 missingness, and molecular or other prognostic features.

Direct comparison with established clinical prognostic tools such as PREDICT and the Nottingham Prognostic Index should be undertaken when their required inputs can be reconstructed consistently across cohorts. A natural extension is a sequential target-adaptation pipeline in which target probability recalibration is followed by conformal recalibration using disjoint target data. Censoring-aware approaches, including Cox regression, random survival forests, and survival boosting, should be evaluated to use partially observed follow-up more efficiently while preserving a clinically interpretable horizon; such methods do not by themselves eliminate selection concerns. Temporal, geographic, prospective, and workflow-based validation also remain necessary.

VI. Limitations

First, the outcome-eligible TCGA cohort contained only 170 patients; its source internal test contained 34, and the few-shot locked test contained 68. These sample sizes yielded wide confidence intervals and limited the resolution of performance and adaptation estimates. In particular, the TCGA-source direction has lower precision and should not receive evidentiary weight symmetric to the METABRIC-source direction. Reusing one locked test across 30 target-sampling repetitions enabled controlled comparisons, but the reported percentiles are conditional on that fixed test and quantify adaptation-sample variation rather than test-population uncertainty.

Second, only 170 of 825 TCGA patients and 1,917 of 2,509 METABRIC patients met the binary 5-year outcome rule. In TCGA, 648 patients were excluded because they were alive or censored by 60 months, and seven had invalid or missing overall-survival months. The resulting complete-outcome analysis may represent a selected subset; no censoring-aware survival model was fitted.

Third, the shared predictor set contained only age and ER, PR, and HER2 status. This deliberate restriction enabled transparent cross-cohort semantic alignment but excluded important prognostic and molecular information. Tumor stage was not used because TCGA TUMOR_STAGE represented T categories, and no supported overall-stage mapping was available; cohort-specific receptor, particularly HER2, missingness also remained. Alternative stage or HER2 harmonization strategies were not evaluated.

Fourth, the detailed calibration, conformal, domain-shift, and few-shot analyses were performed only for METABRIC-to-TCGA transport using the soft-voting model; equivalent reverse-direction uncertainty analyses were not performed. The reported ten-bin ECE is a descriptive, bin-dependent calibration summary and is particularly sensitive to finite-sample variation in the 170-patient external TCGA cohort. Calibration intercept and slope as external-validation measures, flexible calibration curves with uncertainty bands, and comparison with a prevalence-only Brier reference were not part of the accepted analysis. Brier-score and log-loss results remain complementary but do not remove these limitations.

Fifth, the fixed 0.5 threshold was only a descriptive operating point. Threshold-dependent sensitivity and specificity, including zero specificity in several RBF-SVM evaluations, must not be interpreted as recommended clinical operating points. Although frozen patient-bootstrap outputs contain confidence intervals for sensitivity and specificity at 0.5, no clinical threshold optimization or uncertainty analysis around a clinically chosen threshold was performed, and no decision-curve or net-benefit analysis was conducted.

Finally, target probability recalibration estimated both slope and intercept and was unstable at very small N. The accepted exploratory design evaluated probability recalibration and conformal-threshold adaptation as separate branches to isolate their respective effects while maintaining the locked evaluation boundary; a combined probability-plus-conformal target-adaptation pipeline was not evaluated. Direct comparison with PREDICT or the Nottingham Prognostic Index was also outside scope because the required inputs could not be reconstructed consistently from the deliberately restricted harmonized predictor set. This retrospective two-cohort study included no prospective, temporal, geographic, workflow-embedded, subgroup-fairness, or clinical-impact validation. Clinical deployment readiness cannot be inferred.

VII. Conclusion

Using age and receptor status, machine-learning models showed observed numerical decreases in ROC-AUC in both METABRIC-to-TCGA and TCGA-to-METABRIC transport. Both decreases were approximately 0.088, but their 95% confidence intervals included zero. Source-only Platt calibration improved the observed internal probability metrics but produced worse observed external Brier score and ECE. Source split-conformal prediction showed external empirical undercoverage in TCGA, reaching 81.8% rather than nominal 90% coverage. Exploratory few-shot target recalibration improved locked-test Brier score and ECE at larger N, but target conformal-threshold adaptation did not restore mean 90% coverage. These findings support separate evaluation of discrimination, calibration, and uncertainty under cohort shift and do not establish clinical usefulness or deployment readiness.

DATA AVAILABILITY

This study used patient-level and sample-level clinical data for cBioPortal study identifiers brca_metabric and brca_tcga_pub, retrieved through the official REST API on 9 August 2026 (UTC). No mutation, expression, copy-number, imaging, or complete study-archive data were used. Source clinical data remain available through cBioPortal subject to the originating studies' data-use terms; no raw protected, private, or directly identifying data are redistributed with the reproducibility archive.

CODE AVAILABILITY

The executable analysis workflow comprises numbered Python scripts, fixed environment requirements, machine-readable aggregate result tables, split-manifest hashes, and figure-generation code. A publication-ready release candidate has been prepared for author deposit, but no paper-specific public repository URL, release tag, commit, or archival DOI was verified at camera-ready preparation; consequently, no public identifier is claimed here.

ETHICS STATEMENT

This study was a secondary analysis of publicly available, de-identified clinical data obtained through cBioPortal. No new participants were recruited or contacted, and no directly identifying information was accessed. Ethical approval and informed consent for the original data collection were governed by the respective METABRIC and TCGA study protocols.

FUNDING

This research received no external funding.

CONFLICT OF INTERESTS

Unmasking the Unknown: Feature-Orchestrated Image Synthesis for Deep Learning-Based Threat Detection

Sruthi C K, Harini Sriraman*
School of Computer Science and Engineering, Vellore Institute of Technology, Chennai Campus, India

***Abstract*—IoT cybersecurity is crucial as a vast number of linked, susceptible devices serve as possible entry points into bigger networks. Recently, deep learning and machine learning have been used to detect both known and unknown threats. These models suffer from false positives, outdated datasets, biased evaluations against similar attacks, and an inability to generalize against unknown attacks. This study proposes Feature-Orchestrated Image Synthesis (FOS), a technique that selects key features via an explainable AI method, SHAP, then arranges them by tiling the scaled feature value across the row, and then repeats this process with each feature value to guide the image synthesis. SHAP offers a single framework that can be applied to both local and global interpretations. Benchmark datasets BoT-IoT and CICIoMT2024 were used to evaluate the models, InceptionNet and Vision Transformer (ViT). The models were trained only on Denial-of-Service attack and normal traffic images. Our proposed SHAP-ordered approach effectively prioritizes high-influence features, ensuring dependable performance and consistent detection accuracy even in complex, unbalanced network settings. Using the ViT and InceptionNet architectures, it significantly improves detection capabilities over the full features baseline across both CICIoMT2024 and BoT-IoT datasets, yielding recall improvements of 50.2% for ARP attacks and 10.8% for reconnaissance on ViT, along with a 19.0% boost in OS Fingerprint recall on InceptionNet.**

***Keywords*—Unknown attack; pretrained CNN; vision transformer; feature selection; correlation coefficient; SHAP**

I. Introduction

Attacks against the Internet of Things (IoT) take advantage of vulnerabilities in devices linked to the internet in order to obtain illegal access, disrupt operations, and steal data. Attackers have two options for breaking into a network: known attacks and unknown attacks. Security systems are able to identify known threats [1] such as malware and Denial of Service (DoS) attacks. Unknown attacks are novel or modified attack techniques that security systems have never seen before. They are also known as zero-day attacks or exploits. Attacks have long been detected using deep learning and machine learning algorithms. Deep learning techniques are effective at identifying new or zero-day attacks where traffic trends shift from the training distribution, even though both machine learning and deep learning models can successfully identify known attacks by identifying pre-observed patterns. Moreover, deep learning systems are naturally better at scaling to manage massive amounts of high-dimensional network traffic. For unknown attack detection, the models are trained on a particular type of attack and tested on different types of attacks. These attacks may be related to the ones the model has been trained upon, or there may also be a few attacks that are dissimilar to the trained ones. Any type deviating from the training input can be considered unknown. In this way, most of the previous works have given good performance against attacks that are either variants of or attacks that are similar to the training set. In the case of attacks that are unrelated, comparatively, the models have not been able to give decent performance. Both image and non-image forms of inputs to identify the pattern have been given to the models. The performance drawback with respect to unrelated unknown attacks points towards a lack of generalization capability of the models. Feature selection is included under feature engineering. Feature selection techniques include filter methods, wrapper methods, and embedded methods [2]. Additionally, IDS processes large amounts of data quickly, which inevitably increases the processing cost to determine whether the data is malicious or benign. Effective and fast feature selection techniques are therefore required, especially in order to identify zero-day threats. In order to optimize IDS datasets, feature selection is essential. The computational load on IoT devices can be greatly decreased by identifying and keeping only the most important features that affect detection accuracy. By removing unnecessary or redundant data, lowering dimensionality, and accelerating the learning process, it improves model performance. Among the various advantages of feature selection is an improvement in generalization capability by overcoming overfitting. Previous works related to unknown attack detection have highlighted results where different attacks from the same family of attacks [3] technically qualify for the term unknown attack. But these models tend to fail when given an unknown attack from a different family. There is also the case of false positives for the models, wherein normal traffic gets misclassified as an attack. Machine learning models [4] exhibit good performance, but they lack the ability to scale to large volumes of network data if implemented in real time. In order to detect zero-day attacks, this work employs Feature Orchestrated Image Synthesis (FOS), followed by deep neural networks, InceptionNet, and Vision Transformer (ViT). Shapley Additive Explanation (SHAP) is used in the FOS, an Explainable AI (XAI) approach to select important features from the dataset, arrange them by tiling the scaled feature value across the row, and then repeat this procedure with each feature value to direct the picture synthesis process. While LIME (Local Interpretable Model-Agnostic Explanations), another XAI technique, only provides

*Corresponding author.

local interpretation, the SHAP technique has the advantage of providing both global and local interpretation. When compared to scenarios where all features were employed or where the correlation coefficient technique was used for feature selection, the suggested approach produced better detection performance. The contributions of this study are as follows:

- Feature-orchestrated Image Synthesis by using the XAI method, SHAP for selecting key features, arranging them by tiling the scaled feature values across the rows, and then repeating this step for all the feature values, thereby guiding the image synthesis process.
- The features are structured spatially according to their functional characteristics (e.g., statistical metrics, packet headers, and control flags).

The study has the following sections: Section II contains related work, Section III contains methodology followed by results and discussion, and the last section gives the conclusion and future work.

II. Related Works

A. Known Attacks

Using Autoencoders, Saranya, K. Et Al. [5] Carry out Cross-layer Attack Detection of Assaults Linked to Several Network Layers, Such as DDoS and Man-in-the-Middle (MiTM). in This Study, an Autoencoder Has Been Employed for Both Anomaly Detection and Feature Extraction. a Comparison of ML and DL Models Was Presented in the Study [6]. Although DL Models Outperform ML Models, Their Precision, Recall, and F1 Score Only Range from 65 to 70%, Which Is Unsatisfactory. The use of Hybrid Models, Such as Support Vector Machine (SVM)for Multi-class Classification and Deep Belief Network (DBN) for Feature Extraction, in Conjunction with Adversarial Training, Was Suggested in the Study [7].

B. Unknown Attacks

Al-Zewairi et al. [8] proposed the use of a multi-stage, multi-layer zero trust architecture that combines supervised and unsupervised learning stages. The study made use of DBSCAN (Density-Based Spatial Clustering of Applications with Noise), an unsupervised machine learning model. One of the drawbacks of this model is that a single set of parameters can be applied if all clusters are of equal/uniform density throughout the dataset, and it is not scalable. Using Pearson's Correlation Coefficient (PCC) for feature selection, Hakami et al. [9] discovered that RF and Long Short-Term Memory (LSTM) outperformed other models when evaluated on the WSN-DS, UNSW-NB15, and CIC-IDS2017 datasets. Using Enhanced Grey Wolf Optimization (EGWO) for feature selection, Alqahtany et al. [10] proposed random forest (RF) for intrusion detection on the NF-ToN-IoT dataset, achieving an accuracy of 99.93% by choosing 23 features from the dataset. In a different study, Akuthota et al. [11] assessed their attention-based transformer using the NSL-KDD and UNSW-NB15 datasets, achieving 99% accuracy in binary and multi-class classification. The RTIoT2022 dataset was used by Benmalek et al. [12] for a number of models, including CNN, LSTM, K-Nearest Neighbors (KNN), Naïve Bayes (NB), and Categorical Boosting (CatBoost). Out of all the models, CatBoost did the best. In this work, optimization and feature selection were also used. XGBoost (XGB) was proposed by Bikila et al. [13] as a classifier and an autoencoder for feature extraction. On the CICIoT2023 and CICIDS2017 datasets, it attained an accuracy of 99%. A hybrid ML-DL framework that includes CNN and decision trees was used by M. R. Minhas et al. [14] to detect distributed denial of service (DDoS) attacks. For the CICDDoS2019 and CICIDS2017 datasets, they attained an accuracy of 96%. A hybrid ML-DL framework that includes CNN and decision trees was used. For the CICDDoS2019 and CICIDS2017 datasets, the accuracy was 96%. Combining CNN with LSTM models, where CNN is used for feature extraction and LSTM is a classifier, was suggested by Smmarwar et al. [15]. Here, the model identified many kinds of malware families. A hybrid model of soft ordering-based CNN (SOCNN) with outlier identification methods was applied to the BoT-IoT, CICIDS-2017, and CIC-IDS-2018 datasets in study [16]. Its maximum average F1 score was 98.94%. L1 and L2 regularization with CNN was used in another study by Hairab et al. [17] to boost generalizability to identify unidentified threats. They used just nine features from the BoT-IoT dataset. Bot-IoT and N-BaIoT datasets have been subjected to federated learning (FL) [18], which has the benefit of protecting privacy. It was employed to detect zero-day botnet attacks. Both machine learning and deep learning models have been used to identify known and unknown threats on IoT networks. Despite this, both types have demonstrated good performance for a variety of benchmark datasets when employed separately or in an ensemble mode. The inability of machine learning algorithms to handle changing data patterns and scale enormous amounts of data is a disadvantage. Some of the investigations have made use of out-of-date simulation-based datasets that may not reflect network activity in real time. Additionally, it has been noted that certain works have detected unknown attacks that have similarities to the attack that is included in the training set. In our work, feature-orchestrated image synthesis is done by using the XAI method, SHAP, to select key features, followed by arranging the feature values by tiling the scaled feature values across the rows and repeating this process for every selected feature, thus guiding the image synthesis process. The model's performance has been compared to scenarios in which feature selection was not used, utilizing the correlation coefficient and earlier SOTA studies.

Our work introduces a more stringent cross-category assessment methodology, whereas earlier studies have often tested models on unknown attacks that show substantial behavioral similarities or are in the same family as the training distribution. In particular, our models are trained solely on volumetric Denial-of-Service (DoS) behavior and tested on structurally unrelated protocols and intrusion types, such as ARP spoofing, reconnaissance, and OS fingerprinting, where the underlying traffic profiles and feature value distributions are fundamentally different, instead of testing on intra-family variants.

III. Methodology

The following section explains the steps taken to implement the proposed work.

A. System Description

1) Dataset description: In this proposed research, two datasets have been utilized, CICIoMT2024[19] and BoT-IoT [20]. Both datasets have been created by the Canadian Institute of Cybersecurity. A specialized subset called the CICIoMT2024 dataset concentrates on the particular setting of the Internet of Medical Things (IoMT).

- Researchers at UNSW Canberra Cyber developed the BoT-IoT dataset, a large-scale, labeled network benchmark dataset. It contains attacks such as DoS, DDoS, reconnaissance, and information theft. For each network flow, the dataset monitors 46 different statistical and behavioral characteristics.
- A practical benchmark dataset for Internet of Medical Things (IoMT) devices is the CICIoMT2024 dataset. This dataset was created utilizing an IoMT testbed of 40 IoMT devices and included attack categories: mainly DDoS, DoS, reconnaissance, and spoofing. It includes 47 features. All the features are numerical data.

Table I gives the number of samples across attack and normal sets of individual datasets.

The steps followed in the proposed methodology are as follows:

Step 1: Dataset preprocessing: Following feature selection, removal of NaN or any undefined/unrepresented values. Also performed label encoding to convert categorical values to numerical ones, if any are present within the dataset.

Step 2: Feature-Orchestrated Image Synthesis (FOS): Step 2.1: Feature Importance: To select the most relevant, non-redundant, and informative subset of features from the dataset, feature selection techniques have been applied. Feature selection also helps in increasing the unseen attack resilience of the model against unknown attacks. Correlation coefficient [21] and SHAP (Shapley Additive Explanation) [22] techniques were applied to perform feature selection.

- Correlation Coefficient: Features from the dataset are chosen using correlation coefficient values related to the type of assault. We used a two-stage feature selection pipeline to improve model interpretability and decrease multicollinearity: first, redundant features were eliminated by finding pairs with an absolute correlation coefficient greater than 0.90; second, we kept only those features that showed a significant linear relationship with the target variable, as determined by an absolute correlation threshold of 0.1. Based on the correlation coefficient, 12 relevant features for the CICIoMT2024 dataset and 7 relevant features for the BoT-IoT dataset were chosen.
- SHAP, a component of eXplainable AI (XAI), aids in understanding the model's predictions. The model, it offers both local and global forecasts. Another XAI model is LIME; however, it focuses on how the model is interpreted locally. Only the training data—consisting of normal traffic and Denial-of-Service (DoS) attacks—is fed into a tree-based model (Random Forest Classifier) to calculate the SHAP values. The feature significance values derived from this training subset are then used to choose the most important characteristics. Using these SHAP feature importance values, the 12 most relevant features from CICIoMT2024 and BoT-IoT are selected for further processing.

Functionality-based feature ordering: Network traffic metrics can be methodically arranged into coherent functional categories by combining feature rankings obtained from both linear statistical dependencies (like correlation coefficients) and game-theoretic attribution techniques (like SHAP). This domain-aware taxonomy organizes variables into basic operational dimensions instead of depending on isolated, unrestricted feature lists: Packet timing and pacing are captured by Temporal & Duration Metrics; traffic intensity and cumulative byte movement are measured by Volume & Sequence Metrics; low-level connection states and header properties are defined by Structural & Protocol Identity; and complex multi-feature interactions, TCP control flags, and connection distributions are modelled by Statistical & Aggregated Behavior. By connecting the underlying network mechanics with the raw algorithmic output, this structured alignment improves model interpretability and reduces multicollinearity within operational groups. Table II summarises the features selected based on the Correlation Coefficient and SHAP model.

Step 2.2: Train-validation and test split: The training and validation set contains DoS attacks and normal traffic, while the testing set includes the remaining attacks available in the dataset. The train-validation split is a random stratified split that is applied to the pool of normal traffic and DoS attack samples using scikit-learn's train_test_split with the stratify option at an 80:20 ratio. While training using the BoT-IoT dataset, since there is an imbalance between normal and attack traffic, the penalty weight concept has been applied. A penalty weight that is inversely proportional to class frequencies is computed. The neural network is forced to prioritize learning its distinctive characteristics equally because minority classes are given a higher weight. This means that if the model incorrectly classifies a rare attack sample during training, the loss penalty is significantly increased.

Step 2.3: Image Synthesis: In order to create an image, the selected feature values are scaled to a range between 0 and 255. Each scaled feature value is taken and assigned to every pixel across the entire row of the image. This means that an ith feature value is repeated over the entire ith row. This way, a pattern is formed with the selected features. The images are stored with files named "Attack" or "Normal." This is followed by training, validation, and testing sets.

A deterministic image synthesis pipeline is used to convert the tabular network traffic records into spatial visual representations appropriate for Deep Learning architectures. To ensure robustness against unexpected attack outliers, feature vectors are first scaled and clipped into the range [0.0, 1.0] using global minimum and maximum values that are only generated from the training set. The features are sorted in a functionality-based sequence according to their declining SHAP feature relevance score for a given sample with N

selected features. The initial $(N \times N)$ 2D grid matrix, where the i-th feature value uniformly spans the whole i-th row, is created by replicating the scaled features' $(N \times 1)$ column vector across N columns using pixel repetition.

This grid is mapped through the perceptually uniform viridis colormap to create a 3-channel RGB image representation and the necessary 96x96x3 RGB tensor. The image is accurately scaled to 96x96 pixels using nearest-neighbor interpolation (Image.NEAREST) because the feature dimension N does not divide 96 evenly. In order to maintain the structural integrity of the spatial patterns, this resampling technique is essential since it maintains distinct boundaries and stops color leakage across feature rows. The generated photos are then classified as "Attack" or "Normal" and placed in the appropriate directories for testing, validation, and training.

Step 3: Classification model: Pretrained CNN and Vision Transformer models have been used for training and testing the models against attacks that are different from the training ones. The number of epochs for training the models has been decided through the early stopping technique. In the case of the BoT-IoT dataset, there exists an imbalance with respect to attack and normal traffic in the training set; hence, penalties based on class weights are applied to prevent the model from being biased towards the minority class. Vision transformer: Vision Transformers (ViT) [23] have recently emerged as a competitive alternative to the state-of-the-art (SOTA) Convolutional Neural Networks (CNNs) in a range of image recognition and computer vision tasks. The self-attention mechanism must be incorporated into the transformer architecture in order to detect contextual information and long-range linkages in the incoming data. Because a ViT model relies on a self-attention mechanism, it can concentrate on different portions of the input data. Transformer blocks, which include a multilayer perceptron (MLP) head, patch embedding, positional embedding, and a multi-head self-attention layer, are the fundamental elements of ViT. In this work, a patch size of 16 is employed. This particular patch size was selected because it evenly divides the 96×96 picture dimensions, creating a structured 6×6 token grid that is consistent with normal ViT configurations and efficiently captures both global spatial relationships and local feature groupings. This last layer has been modified to produce a binary classification result. InceptionNet: Also called GoogLeNet [24]. With many convolution filter sizes (1 x 1, 3 x 3, and 3 x 3, 5 x 5), the "inception module" was introduced. The computational costs are also reduced by this. InceptionNet is available in multiple versions. Because InceptionNet is computationally efficient, reduces overfitting, and improves accuracy, it outperforms other pretrained models. These pretrained models can be modified to meet the demands of a particular task.

Fig. 1 depicts the flowchart of the entire proposed method. Image_CorrCoeff represents correlation coefficient-based image synthesis, and Image_SHAP follows SHAP feature importance for image synthesis of attack and normal traffic. Table III gives details about various characteristics of the models. Table IV lists the hardware and software specifications used for this work.

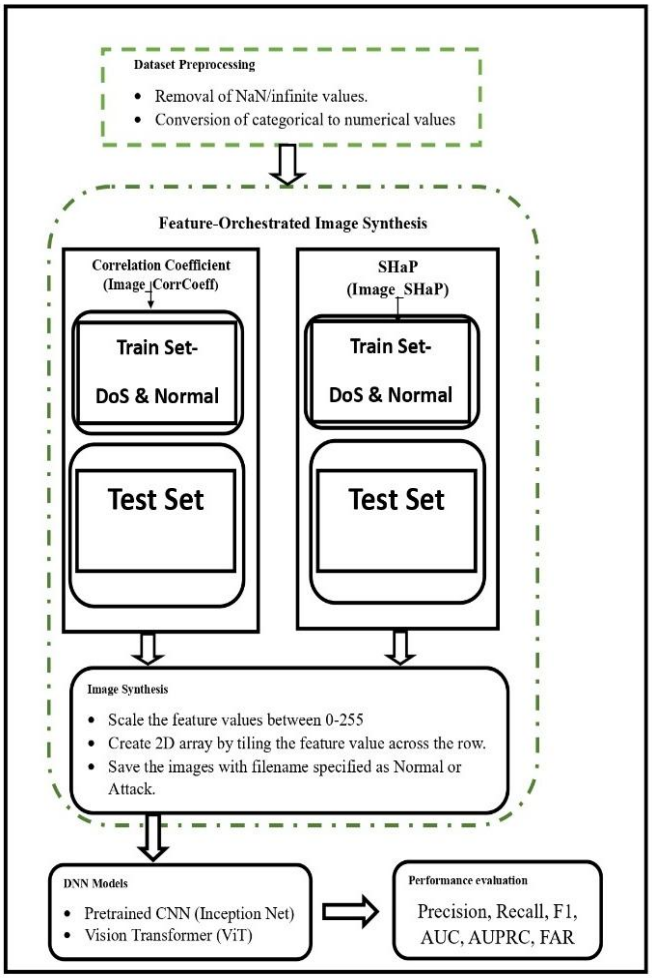

Fig. 1. Flowchart for proposed work.

TABLE I. NUMBER OF SAMPLES OF ATTACK/NORMAL TRAFFIC IN DATASETS

Dataset	Category	DoS	ARP Spoofing	Reconnaissance	OS FingerPrint	Service Scan
CICIoMT2024	Attack	10000	1744	>10000	-	-
	Normal	10000	5000	>2000	-	-
BoT-IoT	Attack	10000	-	-	>10000	10000
	Normal	200	-	-	100	100

TABLE II. FEATURE LIST BASED ON DIFFERENT FEATURE SELECTION TECHNIQUES

IV. RESULTS AND DISCUSSION

The outcomes of the models for classification utilizing images made with various feature subsets according to the number of features are explained in this section. The outcomes have been contrasted with cutting-edge research. Balanced accuracy, precision, recall, False Alarm Rate (FAR), and Receiver Operating Characteristic (ROC)-AUC value are the performance metrics [29] used for assessment.

- Balanced accuracy: When working with unbalanced datasets—that is, where one class significantly outnumbers the others—a performance metric known as balanced accuracy is utilized to evaluate classification models. The arithmetic mean of Sensitivity (True Positive Rate) and Specificity (True Negative Rate) is known as balanced accuracy.
- Recall (True Positive Rate, Sensitivity): Recall gauges the system's ability to recognize each actual attack. The formula is True Positives/ (True Positives + False Negatives).
- FAR (False Alarm Rate): Also referred to as the False Positive Rate (FPR), it measures how frequently the system misidentifies normal, benign traffic as a hostile attack. FAR stands for False Positives/Actual Negatives.
- ROC-AUC value: The ROC AUC score is a statistic that may be used to summarize a classifier's performance across multiple thresholds. The score is calculated by measuring the area under the ROC curve. The ROC AUC score ranges from 0 to 1. Perfect execution is given a score of 1, while random guessing is given a score of 0.5. If a model's score is slightly higher than 0.5, it is considered to have at least "some" (although limited) predictive power. In general, this is not enough for any real-world applications.

TABLE V. EVALUATION BASED ON PREVIOUS WORKS CICIOMT2024 DATASET

Method	Year	Performance Evaluation	Remarks
[25]	2026	Multi-stage evaluation (AE, Binary, Categorical, Multiclass accuracy/success rates. XGBoost achieves a 90.87% success rate on the held-out attack.	1. Framework for multi-stage learning to identify both known and unknown IoMT attacks. 2. Combines hierarchical attack attribution with swift anomaly detection. 3. Assessed using open-set novelty handling in IoMT security scenarios.
[26]	2025	Accuracy: 97.31%	1. Computational overhead is high. 2. 1D CNN is used. 3. Not A Zero-day work. 4. Examined multiple datasets.
[27]	2026	AUROC-OOD of 0.975 with an FPR@95%TPR of 7.8%	1. Open-set recognition 2. Zero-day threat

			3. Evaluation on unseen testbeds. 4. Focuses on time-series protocol compliance over 1D-to-2D spatial image transformations.
[28]	2025	Validation accuracy of 99.23% for CICIoMT2024	1. Focuses strictly on sequential time-series modelling and temporal dependencies. 2. Bidirectional Gated Recurrent Unit (BiGRU), Long Short-Term Memory (LSTM), and Multi-Head Attention (MHA) for sequential time-series feature modelling.
Proposed Work		Balanced Accuracy: 1. For ViT (ARP spoofing): 84.00%, and reconnaissance attack is 90%.	1. Zero-day model. 2. Achieves a +25.86% (InceptionNet) and +47.37% (ViT) balanced accuracy improvement over unordered baselines via SHAP ordering. 3. Balanced accuracy improved via SHAP ordering.

A. Result Analysis of CICIOMT2024 Dataset

The integration of SHAP-based feature selection with the Vision Transformer (ViT) architecture produces the most reliable results for IoMT ARP attack detection, as shown in Table VI. Specifically, the SHAP-ViT configuration achieves an Attack F1-score of 76% and a Balanced Accuracy of 84%, far outperforming baseline models trained on all attributes. Additionally, this technique significantly lowers the low recall rates observed in other architectures by raising the attack recall to 77% while maintaining strong discriminative power with an AUC of 0.87 and an AUPRC of 0.80. Table VII comparative results show that the SHAP-ordered ViT model works better than other setups for reconnaissance scenarios, especially when it comes to capturing attack instances where unordered techniques falter. Spatial feature orchestration is essential for optimizing transformer-based intrusion detection, as demonstrated by the SHAP-based methodology's significant recall improvement (87% versus 65% for the "All features" baseline). Table V gives an evaluation with respect to previous works performed on the same dataset. Fig. 2 displays the plot related to the balanced accuracy achieved for the models

B. Result Analysis of BoT-IoT Dataset

Table IX's comparative analysis demonstrates the ViT architecture's strong detection capabilities in OS fingerprinting situations. For the ViT model, both the SHAP and Correlation Coefficient-guided procedures obtain near-perfect or perfect attack-specific detection metrics; the Correlation Coefficient Ordered and SHAP-guided (ordered and unordered) approaches attain a 100% Attack F1-score. Table X demonstrates that the ViT model achieves 100% Attack F1-score, Recall, and Precision for BoT-IoT service scan assaults both under the baseline "All features" setup and employing the SHAP Ordered approach. These results demonstrate how feature organization techniques, especially SHAP-guided techniques, efficiently optimize the Vision Transformer's ability to identify scan-based reconnaissance. Table VIII performs a comparison of the proposed work with existing ones done with the BoT-IoT dataset. Fig. 3 displays the plot related to the balanced accuracy achieved for the models.

C. Discussion

Machine learning and deep learning models are generally trained and tested on the same attacks, and they don't have generalization capability, especially supervised models. In this work, we have used pretrained CNNs, InceptionNet, and ViT, which were trained only on DoS attacks and normal traffic and tested on different attacks, such as ARP and reconnaissance attacks. The network traffic is organised as an image and given as input to the models. Five cases are considered to compare the results: images synthesized from all features, features selected based on the correlation coefficient, and SHAP. Further features selected from the correlation coefficient and SHAP are taken as an unordered, functionality-based arrangement. It can be understood that not just selecting the features plays a role in improving noise filtering or improving computational efficiency, but their positioning further helps the models in understanding the spatial correlation existing among the features, thereby preventing the model from overfitting to specific attack noise by forcing it to learn the basic architecture of malicious traffic. Even if the particular "unknown" attack does not precisely match a DoS signature, the ViT can use its self-attention mechanism to focus on consistent, high-importance traffic anomalies that distinguish malicious intent from benign behavior when these primary-attack features are arranged structurally within the 2D image. When it comes to capturing local spatial connections, the Inception architecture excels. The InceptionNet is successfully presented with a "canonical" representation of a network anomaly when features are ordered functionally. This gives the model a consistent contextual anchor that helps it distinguish variants that it was not specifically trained to recognize. The SHAP-guided feature arrangement outperforms the 'All features' baseline in both attack types, with the ViT model's recall rising from 19% to 77% for ARP attacks and from 65% to 87% for reconnaissance attacks in the CICIoMT2024 dataset. It also achieves notable improvements in Balanced Accuracy and F1-score for both the Inception Network and ViT architectures. For BoT-IoT dataset, the SHAP-ordered feature arrangement consistently improves detection performance in both OS fingerprinting and service scan attack scenarios. Specifically, it increases the InceptionNet model's balanced accuracy from 65% to 99% for OS fingerprinting. At the same time, it allows the ViT model to reach peak 100% metrics in recall and F1-score for attack detection

D. Impact of Feature Selection and Spatial Ordering

When analyzing previously encountered attack types, feature subset selection (especially via SHAP) consistently improves attack resilience over the 'All features' baseline by effectively removing background noise. Additionally, by organizing similar network features into nearby neighborhoods, functional spatial layout plays a critical role. This spatial ordering significantly improves performance for the Vision Transformer (ViT). In difficult scenarios such as the CICIoMT2024 ARP Spoofing attacks, SHAP-guided ordering increased ViT's balanced accuracy by approximately 17% (from 67.20% to 78.60%) and its F1-score from 48.60% to 68.40%. Similarly, for Reconnaissance traffic, ViT's balanced accuracy improved to 87.60% and F1-score to 91.00%. This performance gain occurs because global self-attention is largely dependent on structured inter-feature layouts. Although its sliding-kernel and pooling mechanisms produce a more localized and varied response to overall spatial positioning, InceptionNet also benefits from functionality-based grouping; for instance, on the BoT-IoT OS Fingerprint baseline, InceptionNet's balanced accuracy surged by over 54% (from 64.00% to 98.60%), and its F1-score rose from 86.80% to 99.40% when transitioning from raw features to SHAP-ordered configurations.

E. Model Evaluation Across Random Seeds

Each of the experiments was carried out over five distinct random seeds (0, 7, 42, 123, 2026) in order to accurately assess the classification framework's stability, robustness, and reproducibility. In order to ensure that the reported metrics accurately reflect model performance rather than lucky weight initializations, this multi-seed evaluation protocol evaluates performance variance across both the baseline "All Features" configuration and the SHAP-ordered feature arrangement for the InceptionNet and Vision Transformer (ViT) architectures. For the CICIoMT2024 dataset, for recall metrics on ARP spoofing, where standard deviations can reach $\pm 24.08\%$ in ViT, the baseline configurations highlight that complex features introduce noticeable seed-dependent variance, underscoring the need for structured feature ordering (such as SHAP alignment) to stabilize convergence. Adopting the SHAP-ordered arrangement significantly improves performance and stabilizes consistency, increasing balanced accuracy to $98.60 \pm 0.55\%$ and recall to $98.80 \pm 0.45\%$, while the All-Features baseline configuration for InceptionNet on OS Fingerprint detection suffers from high seed instability ($64.00 \pm 2.45\%$ balanced accuracy and $\pm 32.33\%$ recall variance). While the All-Features baseline for service scan detection using InceptionNet already achieves a respectable balanced accuracy of $85.60 \pm 6.84\%$, using the SHAP-ordered feature arrangement significantly reduces variance and stabilizes performance, resulting in a more consistent balanced accuracy of $85.40 \pm 0.55\%$ with zero recall fluctuation ($\pm 0.00\%$). Table XI and Table XII show the performance across different metrics using random seed evaluation for both datasets.

V. Conclusion

Model generalization is an important challenge, particularly when it comes to network attack detection, since the attacker may launch a known attack differently. Therefore, the deep learning models should be ready for both known and unknown threats (related or unrelated to the attacks on which the model was trained). This study tries to enhance the performance of the model by utilizing a feature-orchestrated image synthesis technique on two benchmark datasets, BoT-IoT and CICIoMT2024, which include DoS, reconnaissance, and ARP spoofing attacks. FOS used the XAI technique, SHAP, a better model than LIME for performing local as well as global interpretation. Feature importance-based on DoS attacks and normal traffic is calculated, and the most relevant features are taken. These feature values are further scaled and tiled across a row, and the process is repeated for all feature values, thereby guiding the image synthesis process. These images are given to InceptionNet and ViT for the detection process. The

performance of the models is compared to image synthesis performed without any feature selection, as well as image synthesis using the correlation coefficient. In image synthesis using the correlation coefficient, selected features were correlated to DoS attacks. A balanced accuracy improvement of 25.86% for InceptionNet (from 59.00% to 74.20%) and 47.37% for ViT (from 67.20% to 99.00%, or relative gain calculations mapped from baseline to the structured configuration) is obtained for ARP Spoofing attack detection by implementing the SHAP-ordered feature arrangement over the baseline. The SHAP-ordered strategy consistently optimizes with a high F1 score of $87.00 \pm 0.00\%$ for service scan attack detection using InceptionNet, while ViT consistently performs well throughout assessment runs. It can be understood that feature-orchestrated input has a role in improving the unseen attack robustness of a model, especially for a supervised one. Future work can include the use of semi-supervised models to help the supervised model improve its generalisation capability

Arabic Text Simplification and Readability Assessment for Educational Applications: A Systematic Literature Review

Khalid Essaadani, Soumia Ziti
Mohammed V University in Rabat, Morocco

***Abstract*—Arabic text simplification and readability assessment support level-appropriate material selection, language learning, early literacy, teacher adaptation, and accessibility, but the degree of educational validation remains uncertain. This PRISMA 2020 systematic review searched Scopus, Web of Science Core Collection, and IEEE Xplore on 6 August 2026 and updated coverage through a targeted ACL Anthology search, a standalone-readability sensitivity search, and citation-cluster checking on 11 September 2026. Following source-identity verification, 194 records were identified, 129 were screened, 69 full texts were assessed, and 61 studies were included. An eight-criterion appraisal rated 45 studies high, 13 moderate, and 3 low quality. Thirty-four studies primarily modelled readability, while recent work increasingly used Arabic pretrained language models, ordinal objectives, graph models, large corpora, and controlled generation. Forty-two studies relied primarily on automatic or benchmark metrics; only two directly measured learner comprehension or retelling, and none measured longitudinal learning gain. Excluding low-quality studies and interpreting documented resource reuse did not alter the central conclusion. The retrieved evidence demonstrates technical feasibility and growing educationally relevant resources, but educational effectiveness remains unestablished. Priorities are independent learner and teacher evaluation, cross-domain and cross-variety validation, interoperable scales, human calibration of automatic metrics, and closed-loop diagnosis, simplification, and level verification.**

Keywords*—Arabic text simplification; Arabic readability assessment; educational natural language processing; systematic literature review

I. Introduction

Matching a text to its reader is a central educational requirement. Readability assessment estimates text difficulty or predicts an appropriate reader level; text simplification modifies lexical, syntactic, or discourse complexity while attempting to preserve meaning. In educational systems, the tasks are complementary: assessment can identify a mismatch, simplification can adapt the material, and reassessment can test whether the target level was reached.

Arabic complicates this cycle through rich morphology, optional diacritics, orthographic variation, lexical-frequency effects, and diglossia. Modern Standard Arabic (MSA), Classical Arabic, and spoken varieties place different demands on readers. The relevant populations range from first-language (L1) school readers to Arabic second- or foreign-language learners (L2), university students, emergent readers, teachers, and people who need accessible text.

The central evidence problem is not whether a model improves a benchmark score, but whether the improvement transfers to a defined reader and produces a meaningful outcome. Model accuracy, annotation agreement, and linguistic judgments are necessary forms of evidence, yet they do not by themselves establish comprehension, retention, learning, teacher adoption, or sustained classroom benefit.

A. Background and Prior Reviews

Arabic readability research includes corpus-frequency formulas [3], feature-rich machine learning, leveled corpora, and neural models. Mat Daud et al. propose a formula based on reversed word-frequency ranks, while discussing length-based formulas as prior work [3]. Nassiri, Cavalli-Sforza, and Lakhouaja's survey [1] describes formula-based and machine-learning approaches to Arabic readability for L1, L2, and adult audiences, according to its published abstract.

Building on that readability-focused account, the present review jointly examines readability assessment and text simplification under an educational scope. Its contribution is an explicit connection between study-level technical findings and the kind of educational evidence they provide: resource validity, reader processing, usability, direct learner outcomes, or learning gain. PRISMA selection, criterion-level appraisal, the September 2026 search update, and documented evidence-family mapping make this connection auditable. The earlier survey's full text was unavailable for this revision; this comparison is therefore limited to its published scope and does not assert that particular procedures or topics were absent from it.

Its contributions are a combined synthesis of Arabic text simplification and readability assessment under an explicit educational scope; a reproducible search, deduplication, screening, extraction, and appraisal trail; a taxonomy of educational contexts, computational approaches, resources, and evaluation practices; an evidence-level distinction between technical performance, reader validity, and educational effectiveness; and a prioritized research agenda for learner-centred, teacher-centred, and classroom evaluation.

B. Research Questions

- RQ1: Which educational objectives, learner populations, and application contexts are addressed?

- RQ2: Which computational or analytical approaches, tools, and techniques are used?
- RQ3: Which resources, datasets, annotation schemes, and benchmarks support the field?
- RQ4: How are systems and resources evaluated, and what educational outcomes are measured?
- RQ5: Which evidence gaps and research priorities emerge across the literature?

II. Review Method

A. Review Design and Scope

The review followed PRISMA 2020 [2]. The protocol was developed before the original screening but was not prospectively registered. The unit of inclusion was a peer-reviewed primary journal article or full conference paper examining Arabic text simplification, readability, reading level, text difficulty, or text complexity with an explicit educational, learner-facing, teacher-facing, literacy, or accessibility connection.

Table I states the operational eligibility rules. Retrieval failure was recorded separately and was not treated as a content-based exclusion.

B. Information Sources and Search Strategy

Scopus, the Web of Science Core Collection, and IEEE Xplore were searched on 6 August 2026. Each English query combined Arabic identifiers with phrases for text simplification, readability assessment, reading level, text difficulty, and text complexity. Arabic-script supplementary queries returned zero records. Journal articles and full conference papers were retained through database-specific type filters; no year, country, subject, document-language, or access-status restriction was used.

To test the NLP coverage gap identified during review, the official ACL Anthology title-and-abstract metadata were searched on 11 September 2026 with the original concept blocks. A sensitivity query added the standalone term "readability," which had been omitted originally to limit unrelated uses. The main ACL query returned 25 candidates, and the standalone-readability query returned 16 non-overlapping candidates. Five additional BAREC system papers were located by citation-cluster checking because their searchable metadata did not explicitly repeat an Arabic identifier. After removal of five overlaps with the original set and full-text screening of 41 unique reports, seven were excluded, and 34 were newly included. The standalone-readability search contributed 10 of these inclusions, demonstrating that the term materially improved recall.

TABLE I. Eligibility Criteria and Operational Exclusions

Criterion	Include	Exclude or record separately
Language focus	Arabic is the target language or Arabic results are separable.	Non-Arabic work, Arabic-script work in another language, or multilingual work without separable Arabic evidence.
Target phenomenon	Text simplification, readability assessment/prediction, reading level, text difficulty, or text complexity.	Adjacent tasks in which readability is only incidental.
Educational relevance	Learners, teachers, curricula, material selection, literacy, accessibility, or another explicit learner-facing use.	Domain readability with no defensible educational or learner-facing connection.
Evidence type	Original computational, corpus, system, usability, reader, learner, or pedagogical research.	Editorials, narrative surveys, perspectives, and reviews.
Publication type	Peer-reviewed journal article or full conference paper.	Thesis, abstract-only record, poster, book/chapter, standard, or non-peer-reviewed report.
Assessment	Sufficient full text to judge eligibility and extract evidence.	Unavailable reports were recorded as not retrieved; they were not assigned a substantive exclusion reason.

ACM Digital Library coverage was checked through ACM DOI-prefix metadata because the public interface triggered security verification and did not provide a reproducible export during the revision. Two ranked searches ("Arabic readability" and "Arabic text simplification") identified no unique eligible primary report: two potentially eligible reports were already in the database set, and two Arabic-focused records were reviews. Exact queries, dates, filters, counts, clean copyable Arabic-script strings, and record-level decisions are supplied in the supplementary workbook.

C. Record Management, Retrieval, and Selection

Records were deduplicated first by normalized DOI and then by normalized title, while retaining provenance. Title and abstract records were coded Include, Maybe, or Exclude with a reason; Include and Maybe records advanced to retrieval. Additional attempts for the original 15 unavailable reports comprised publisher/DOI checks, exact-title web and institutional-repository searches, ResearchGate availability checks, and OpenAlex open-access-location verification. A source-identity audit on 16 September 2026 found that the PDF stored for ATSRA-010 [9] was a different publication by the same authors. Publisher and exact-title checks did not yield the intended full text; the linked ResearchGate PDF repeated the mismatch. ATSRA-010 was therefore reclassified as not retrieved, and its extraction and appraisal were withdrawn. The final total is 16 unretrieved reports. This was a retrieval correction, not a content-based exclusion or a new search inclusion. The reports, attempts, and topic-only coverage implications are listed in the supplement. No result, direction, or effect was imputed from an unretrieved report.

D. Data Extraction and Evidence Dependence

For every included report, the extraction table records citation, year, setting, population or educational context, Arabic variety, task, method, dataset and size, readability scale, evaluation design and metrics, principal findings, limitations, and evidence relevant to RQ1–RQ5. Publications were additionally mapped to evidence families. BAREC corpus, guidelines, demo, shared-task, and system papers form a shared

benchmark family; SAMER, DARES/SaudiTextBooks, AraEyebility, ATSC, and the L2/GLOSS research programme also contain repeated or evolving data. Documented reuse is distinguished from related research with unverified participant overlap, including the earlier 2021 eye-tracking pilot. These mappings guide interpretation but do not establish an exact count of independent datasets or participant samples.

E. Quality Appraisal

Eight equally weighted criteria were scored 0, 0.5, or 1: clear aims and educational relevance; description of data/sample/context/Arabic variety; reproducibility; claim-appropriate evaluation; design-appropriate baseline, control, agreement, or validation; clear results and suitable metrics; proximity to intended readers, learners, educators, or users; and limitations/transparency/availability. Criterion-specific anchors are provided in the supplement. For example, Q5 accepts competitive baselines or ablations in computational studies, inter-annotator agreement or held-out benchmarks in corpus studies, and comparison/control evidence in user studies. Q7 deliberately records educational-evidence proximity: direct comprehension, retelling, retention, learning gain, or authentic educator adoption scores 1; indirect human/expert/user evidence scores 0.5; no human evidence scores 0.

Totals of 6.5–8 were classified high (at least 81.25% of the maximum), 4.5–6 moderate (56.25–75%), and 0–4 low (50% or less). These pragmatic thresholds distinguish broadly complete, partially complete, and substantially limited evidence profiles. Quality was not an exclusion rule. High-quality technical studies could strongly support a model or resource claim while remaining weak evidence of educational effectiveness.

F. Review Procedure and Verification

The first reviewer conducted the full screening, data extraction, and quality appraisal. The coauthor then independently re-screened a blinded, stratified sample of 13 of 129 records (10.1%) using the same Include, Maybe, or Exclude categories and eligibility criteria. Exact three-category agreement was 7/13 (53.8%; Cohen's kappa = 0.284). Because both Include and Maybe advanced to retrieval, agreement on the operational advance-versus-exclude decision was 11/13 (84.6%; kappa = 0.683). Four differences were conservative Include-versus-Maybe judgments and did not alter progression. The first reviewer adjudicated all differences against the prespecified criteria and available full texts. ATSRA-017 was changed from Exclude to Include because the protocol explicitly includes accessibility and learner-facing information; SUP-001 remained excluded because text difficulty was used only as a machine-translation performance variable. Extraction and quality appraisal were not independently duplicated and remain a limitation. The screening sample, reasons, agreement calculations, adjudications, complete extraction data, and item-level ratings are supplied in the supplementary materials.

G. Synthesis

A narrative thematic synthesis was organized around RQ1–RQ5. Meta-analysis was inappropriate because populations, tasks, scales, datasets, and outcomes were heterogeneous. Four categories were used: direct learner outcome (comprehension, Cloze, retelling, retention, or achievement in intended learners); reader-processing evidence (eye movements, time, or perceived difficulty without a learning-gain design); usability evidence (workflow or acceptability without comprehension); and learning gain (pre/post or longitudinal improvement attributable to an intervention). Automatic metrics, annotation reliability, expert linguistic judgments, corpus statistics, and demonstrations were classified as technical/resource evidence.

III. Results

A. Study Selection

The original databases yielded 148 records. Supplementary ACL searching and citation-cluster checking identified 46 additional records, for 194 in total. Removal of 65 duplicates left 129 records for screening; 44 were excluded at title and abstract screening. Eighty-five reports were sought, 16 were not retrieved after source-identity verification, and 69 were assessed for eligibility. Eight reports were excluded after full-text assessment (seven supplementary reports outside the review scope and one master's thesis), leaving 61 included studies (Fig. 1) (Table V). The 16 unretrieved reports represented 36.4% of the 44 distinct reports sought through the original database pathway and 18.8% of all 85 reports sought after the update.

B. Study Characteristics and Evidence Structure

The 61 publications appeared from 2013 to 2026; 48 (78.7%) were published from 2022 onward. Table II summarizes the evidence base and distinguishes publication volume from evidential independence. Readability modelling was the largest primary task (n = 34), followed by resource/corpus work and simplification or readability-controlled generation (n = 8 each), tools/systems (n = 6), and human/pedagogical assessment (n = 5). The concentration of 2025 publications partly reflects 18 BAREC shared-task and overview papers that evaluate a common benchmark.

TABLE II. Distribution of the Included Evidence Base

Dimension	Distribution	Total
Quality tier	High 45; moderate 13; low 3	61
Primary task	Readability modelling 34; resource/corpus 8; simplification or controlled generation 8; tool/system 6; human/pedagogical assessment 5	61
Primary evaluation	Automatic/benchmark metrics 42; resource quality 6; system/demo 5; learner/reader experiment 3; expert simplification evaluation 2; usability 1; pedagogical analysis 1; prototype 1	61
Direct educational evidence	Direct learner outcomes 2; learning-gain studies 0	2 direct; 0 gain
Major dependent families	BAREC; SAMER; DARES/SaudiTextBooks; AraEyebility; ATSC; L2/GLOSS	6 mapped families

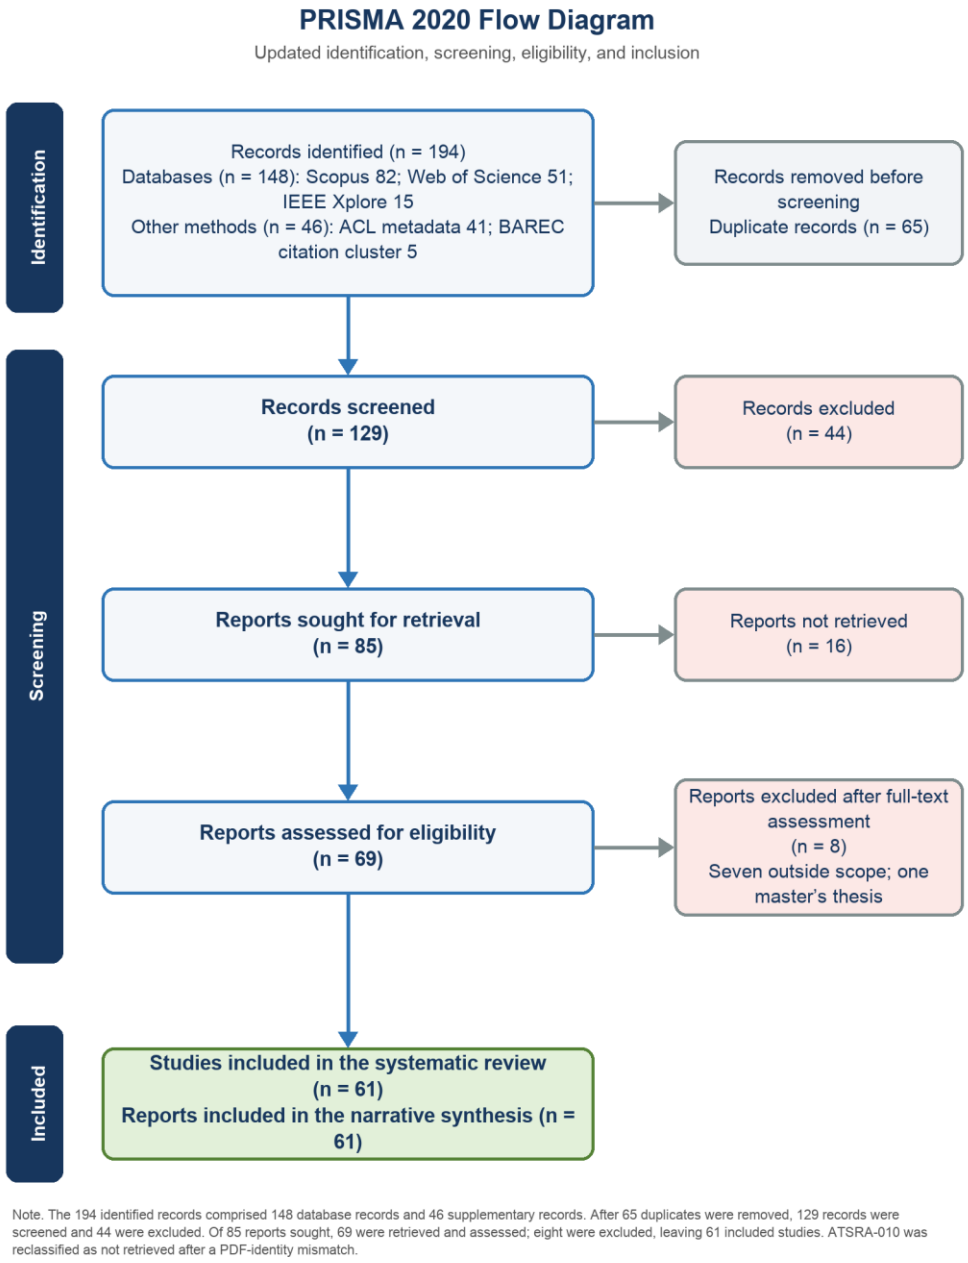

Fig. 1. PRISMA 2020 flow diagram for the updated review.

C. *Quality Appraisal and Quality-Informed Synthesis*

Forty-five studies were high quality, 13 moderate, and three low; the mean was 6.45 of 8. The item-level table shows a recurrent pattern: data, methods, and benchmark results are usually well reported, while Q7 is often zero because intended readers or educators are not evaluated. This does not invalidate technical findings; it limits the claim they can support.

Quality weighting was applied concretely. High-quality BAREC, SAMER, DARES, and cross-domain studies anchor claims about corpus maturity, model performance, and domain sensitivity [4], [15], [29], [37]–[44], [55]–[63]. Moderate-quality demos and accessibility audits describe workflows or text properties but do not establish learner benefit [10], [12], [30], [34], [64]. The three low-quality reports, including the CART prototype [13], contribute historical or design context only and do not anchor any conclusion. Omitting them leaves 58 studies; both direct learner studies remain, no learning-gain study appears, and the conclusion of technical feasibility without established educational effectiveness is unchanged (Table III).

TABLE III. QUALITY-INFORMED SENSITIVITY ANALYSIS

Analysis	n	High/Moderate/Low	Direct learner outcomes	Learning gain	Interpretation
All included	61	45/13/3	2	0	Technical feasibility; effectiveness unestablished
Exclude low quality	58	45/13/0	2	0	Central conclusion unchanged
Account for evidence families	Publication total retained; dependent resources mapped	Family-level interpretation	2 independent learner samples	0	Model volume remains concentrated around shared resources

D. RQ1: Educational Objectives, Learners, and Applications

The literature proposes four principal educational uses. First, readability prediction supports material selection, curriculum grading, and passage matching for school, university, and L2 readers [7], [8], [10], [15], [22], [23], [29], [32], [35], [37], [42], [58]. Second, simplification systems and resources support lexical substitution, sentence rewriting, accessible fiction, religious text adaptation, and readability-controlled generation [5], [6], [10], [25], [29], [36], [39], [45], [56], [57]. Third, tools expose difficulty information to teachers, authors, annotators, and learners through reports, visualization, thesauri, and searchable corpora [10], [12], [16], [30], [34]. Fourth, reader studies examine textbook suitability, early literacy, variety, and cognitive processing [7], [11], [14], [18], [20], [27].

The demonstrated educational impact is much narrower than the proposed use. In the university Cloze study, 54 students completed four unseen textbook passages; passage mean scores ranged from 0.46 to 0.66, and all four passages were classified at the frustration level for that sample [7]. The study directly tests material–learner fit but is limited to one institution and textbook. In the preschool experiment, 30 Arabic-speaking children (mean age 5 years 10 months) encountered four picture-supported narratives that varied in MSA versus spoken Palestinian Arabic and in episodic complexity. Comprehension was higher for MSA, while greater episodic complexity supported longer retellings; these are outcome-specific findings, not uniform effects across all measures [27]. Its direct child evidence is valuable but limited by a small, relatively advantaged sample and four narratives.

These two reports are the only direct learner-outcome studies. The three studies counted as primary learner/reader experiments comprise those two plus one CA–MSA eye-tracking comparison of 15 matched proficient adults: 23 were recruited, 18 retained for MSA, and 15 completed both sessions [18]. Other eye-tracking papers use gaze data primarily for resource construction or prediction [11], [14], [20]. The usability study involved five graduate human–computer interaction students evaluating four existing general readability tools to inform Arabic reporting interfaces, not an Arabic learner intervention [16]. Thus, "three learner/reader experiments" and "two direct learner outcomes" describe different evidence categories and are not conflicting counts. No study measured longitudinal learning gain.

E. RQ2: Methods, Tools, and Techniques

Formula and rule-based work uses surface length, syllable structure, lexical density, word frequency, diacritics, and Arabic-specific factors such as Faseeh. The corpus-frequency formula in [3] draws on KACSTAC (739,119,011 words); this is its source corpus, not a learner-validation sample. OSMAN evaluated an Arabic formula against English readability scores on approximately 73,000 aligned UN text units, described as sentences in its abstract and paragraphs in its methods [31]. These methods are transparent and inexpensive, but formula correlation is not equivalent to learner calibration.

Classical machine learning uses linguistic features with support-vector methods and random forests [17], [21]. SATLab instead combines character n-grams with support-vector regression and optimized ordinal thresholds, providing a non-neural BAREC baseline [60]. Feature optimization reported 94.8% L1 accuracy and 72.4% L2 SVM accuracy in its main setting; its augmented-feature experiment additionally reached 74.1% L2 accuracy with kNN (Table VII in [32]). On the Jordanian School Textbook Corpus, CAMeLBERT reached in-domain QWK 0.830 but fell to 0.085 cross-domain, whereas a 127-feature XGBoost model retained the best cross-domain QWK of 0.240 [58].

Neural approaches include fastText and contextual embeddings, CNN/BiLSTM architectures, Arabic pretrained transformers, graph neural networks, ordinal heads, differentiable QWK losses, conformal decoding, ensembles, and visual text models [19], [29], [35], [38], [40]–[43], [46]–[54], [59], [61]–[63]. In the BAREC shared task, the strongest system reached QWK 0.875 at sentence level and 0.874 at document level [40], [42]. Because 18 reports share BAREC data and tracks, these results compare techniques within one family rather than supplying 18 independent validations.

Simplification methods range from lexical pipelines and embedding-based substitutions to Seq2Seq, mT5, switch transformers, machine-translation hybrids, and prompted LLM generation [5], [6], [25], [29], [36], [39], [45], [56], [57]. The 2023 embedding system reached complex-word identification F1 of 0.88; expert review found that 79% of binary-model outputs were simpler, but the multi-complexity model better preserved meaning (69%) and grammar (84%), demonstrating a real simplification–adequacy trade-off [36]. Controlled CEFR prompting reached high automatic profile alignment [56], but still lacked learner testing.

Human-centred techniques include Cloze testing, narrative comprehension and retelling, expert linguistic judgments, usability observation, and eye tracking. The later AraEyebility corpus and analyses reuse related data [11], [18], [20]. The earlier 41-participant pilot [14] belongs to the same research programme, but participant overlap with the later corpus is unverified. Small samples and documented reuse limit generalization; a shared research programme alone does not establish identical participants.

F. RQ3: Resources, Datasets, and Scales

Resource capacity has expanded substantially. BAREC contains 69,441 sentences and more than one million words across 19 levels, with QWK 0.818 in its final annotation phase [4], [44]; BAREC-10M extends the programme to approximately 10 million words and 45 subcorpora [55]. SAMER contains approximately 159,000 original-corpus words from 15 novels with word/document levels and two simplified versions [39], and its associated lexicon contains approximately 26,000 triply annotated lemmas [33]. DARES 1.0 includes 13,335 curriculum instances [37], while DARES 2.0 expands and cleans concept-centred Saudi textbook data [15]. Other resources include ATSC (500 article/simplification pairs) [6], README++ (9,757 multilingual sentences, including 1,945 Arabic) [24], AraEyebility [11], MoSAR [23], Saaq al-Bambuu (2,980 sentence pairs) [29], and the 82,512-segment, 240-textbook JSTC [58].

Interoperability remains weak. Taha/Arabi21 levels, school grades, the Common European Framework of Reference, Interagency Language Roundtable levels, Cloze thresholds, and bespoke labels differ in target population and unit of analysis. Dataset expansion therefore does not automatically produce transferable educational meaning. Crosswalks should report uncertainty and be validated with intended readers.

G. RQ4: Evaluation and Educational Outcomes

Forty-two publications primarily report automatic or benchmark metrics such as accuracy, macro/weighted F1, QWK, BLEU, SARI, METEOR, ROUGE, BERTScore, or distance from an ordinal label. Six focus on resource quality and five on system or demo functionality. These evaluations can establish technical reproducibility, annotation reliability, or relative performance, but not comprehension or learning.

Evidence categories are exclusive at the primary-evaluation level but are interpreted alongside secondary human evidence. Direct learner outcome requires task performance by intended learners; reader processing requires cognitive or behavioral reading measures without a learning-gain design; usability concerns workflow and acceptability; learning gain requires change attributable to an intervention. The observed counts are two, three, one, and zero, respectively. Expert judgments of grammar, meaning, or annotation quality strengthen linguistic validity but are not learner outcomes.

H. RQ5: Gaps and Priorities

The dominant gap is educational validation: 59 of 61 publications lack direct learner outcomes, and no longitudinal classroom intervention was found. Other priorities are teacher-centred evaluation, external and cross-domain testing, dialect/register coverage, calibration of automatic metrics against Arabic comprehension, transparent cross-scale mapping, and independent replication beyond recurring datasets. Unretrieved reports appear to concern accessibility, early tools, feature/vectorization methods, L2 readability, class balancing, patient education, lexical simplification, and web indices; their absence may narrow historical and applied coverage, but no unobserved result is assigned to them (Table IV).

TABLE IV. EVIDENCE-BASED RESEARCH AGENDA

Priority	Evidence gap	Recommended design	Required outcomes
Critical	Direct learner evidence remains 2/61; learning-gain evidence is 0/61.	Controlled or quasi-experimental studies with intended learners.	Comprehension, retention, reading efficiency, learning gain.
Critical	No longitudinal classroom deployment.	Teacher co-design and sustained authentic-course deployment.	Adoption, workload, instructional decisions, sustainability.
High	Strong benchmark but weak cross-domain transfer.	External validation across curricula, genres, regions, and varieties.	QWK/F1 plus subgroup validity and error analysis.
High	Automatic metrics dominate 42 primary evaluations.	Calibrate metrics against Arabic human judgments and learner tasks.	Meaning, grammaticality, comprehensibility, comprehension.
High	Readability scales are not interoperable.	Multi-scale annotation and transparent probabilistic crosswalks.	Reliability, mapping uncertainty, transfer validity.
High	Publication volume clusters around shared resources.	Independent datasets, preregistered splits, and evidence-family reporting.	External replication and generalization.
High	Few closed-loop educational systems.	Diagnose difficulty, simplify, reassess target level, then test with users.	Target attainment, comprehension, teacher control.

IV. DISCUSSION

A. Principal Findings and Educational Applications

Research on Arabic readability and simplification is rapidly expanding. The updated search reveals a mature technical ecosystem of leveled lexicons, school and literary corpora, annotation tools, visual interfaces, feature-based classifiers, Arabic transformers, ordinal objectives, and controlled generators. It also strengthens—not weakens—the original central message: adding 34 ACL studies increases the amount of technical evidence without adding a direct learner-outcome or learning-gain study.

For material selection and curriculum design, practical evidence combines direct mismatch detection in the university Cloze study [7], child variety/complexity effects [27], school-corpus modelling [15], [37], [58], and textbook classification and gradation analysis [26]. For teacher authoring, tools can flag difficult words, suggest alternatives, expose levels, and search graded corpora [10], [12], [30], [34], while the five-person general-tool usability study offers interface-design guidance rather than educator-adoption evidence [16]. Adoption, workload, and decision quality remain insufficiently measured. For L2 learning, CEFR/ILR/GLOSS work shows feasible automatic leveling [8], [28], [32], [35], yet the labels require calibration to real learners.

For accessibility, the Arabic orthodontic-information audit covered 74 websites and found apparently accessible formula scores but limited reliability of the online information and no direct patient-comprehension test [64]. Other disability and patient-education reports remain unretrieved, so conclusions in these subdomains remain cautious.

Generative systems create a new educational opportunity and a new validity risk. Models can simplify, control grade or CEFR profiles, and diversify early-grade stories [5], [6], [25], [29], [36], [39], [45], [56], [57]. However, automatic level agreement can coexist with factual drift, loss of meaning, cultural mismatch, or inappropriate difficulty for a real learner. Educational deployment therefore requires human evaluation, reader testing, educator control, and post-generation reassessment.

B. Quality, Dependence, and Strength of Conclusions

The quality-informed synthesis prevents high benchmark scores from carrying inappropriate educational weight. High-quality computational studies anchor statements about what works on their datasets; direct learner reports anchor the much narrower statements about comprehension and text–reader fit. The low-quality reports are contextual only. Excluding them does not change the conclusion. Likewise, evidence-family mapping shows that the BAREC surge represents intensive comparison on one valuable benchmark, not many independent populations. Similar caution applies to AraEyebility participant subsets and successive DARES, SAMER, ATSC, and L2/GLOSS outputs.

C. Strengths and Limitations

Strengths include exact database queries, a targeted ACL update, a standalone-readability sensitivity search, citation-cluster checking, explicit record-level decisions, retrieval auditing, study-level extraction, criterion-anchored appraisal, sensitivity analysis, and evidence-family mapping. The supplementary workbook makes each main conclusion traceable to individual reports.

Limitations remain. Sixteen reports could not be retrieved, including one whose stored PDF proved to be a different publication; they represented 36.4% of reports sought through the original database pathway and 18.8% overall after the update. The source-identity error led to withdrawal of that report's extraction and appraisal. ACM coverage was checked indirectly through DOI-prefix metadata because the interface did not permit reproducible access during revision. The protocol was not registered prospectively. Heterogeneity precluded meta-analysis. Independent coauthor re-screening covered 10.1% of records and showed substantial agreement on the operational advance-versus-exclude decision, but only fair exact three-category agreement. Extraction and appraisal were not independently duplicated, so reviewer-dependent judgment may still have affected extracted classifications and quality scores. The comparison with the earlier survey is limited to its published abstract, and some participant-overlap relationships remain unverified. Finally, 2026 indexing is still evolving, and later records may alter counts.

V. Conclusion

Research on Arabic text simplification and readability assessment has progressed from formulas and handcrafted indicators to large, fine-grained corpora, cognitive signals, Arabic pretrained language models, graph and ordinal methods, and readability-controlled generation. These advances create credible tools for level-aware material selection, text adaptation, curriculum analysis, and educational content generation.

They do not yet establish broad educational effectiveness. Only two of 61 included publications directly measured learner outcomes, none measured longitudinal learning gain, and much of the recent model literature reuses a small number of resource families. The camera-ready conclusion is therefore bounded: technical feasibility and resource maturity are supported by the retrieved evidence; improved learning or classroom practice is not. The next phase should connect models to representative learners, teachers, curricula, varieties, and authentic use, while preserving meaning and independently verifying target-level attainment.

Supplementary Materials

The supplementary review data, including the database search log, screening decisions, unretrieved-report audit, extraction table, study-level evidence tables, evidence-family map, quality-appraisal ratings, sensitivity analyses, evidence-category definitions, and independent coauthor verification, are publicly available in Zenodo at https://zenodo.org/records/22829321, DOI: 10.5281/zenodo.22829321.

Declarations

Ethics approval: Not applicable. This review analyzed published literature and collected no new human-participant data.

Funding: This research received no external funding.

Conflicts of interest: The authors declare no conflict of interest.

Data availability: The review dataset and supporting supplementary materials are publicly available in Zenodo at https://zenodo.org/records/22829321, DOI: 10.5281/zenodo.22829321.

Declaration on generative AI: Generative AI tools assisted spreadsheet organization, document preparation, and language refinement. The authors remain responsible for eligibility decisions, evidence interpretation, citation verification, originality, and final content.

APPENDIX A: REPRODUCIBLE SEARCH COVERAGE

The full database-specific strings, filters, dates, and counts are supplied in the Search Log sheet of the supplementary workbook. The ACL update replicated the original Arabic and concept blocks in official title-and-abstract metadata, then ran a distinct sensitivity search using standalone "readability." Arabic-script strings are provided as plain UTF-8 cells to avoid bidirectional corruption in typeset syntax. The BAREC cluster check and ACM DOI-prefix verification are documented separately.

TABLE V. REPRESENTATIVE STUDY-LEVEL EVIDENCE (FULL 61-STUDY TABLE IN SUPPLEMENT)

Study/family	Population, data, or design	Principal finding	Main limitation
ATSRA-007	54 university students; four textbook passages; Cloze	All passages at frustration level; passage means 0.46–0.66	One institution/textbook
ATSRA-077	30 preschool children; four MSA/Palestinian Arabic narratives	Variety and complexity affected comprehension/retelling; MSA higher in tested design	Small advantaged sample; four stories
AraEyebility family	Later corpus/analyses share data; CA–MSA comparison n = 15	Gaze features and register contrasts reveal processing differences	Overlap with the earlier 41-reader pilot is unverified
BAREC family	69,441 sentences; 1M+ words; 19 levels; 18 shared-task/overview papers	Best QWK 0.875 sentence/0.874 document; annotation QWK 0.818	Common benchmark; no learner outcome
SAMER family	Approximately 26,000 lemmas; 159,000 original-corpus words	Supports word/fragment models and two target simplifications	Linked resources; literary-domain limits
DARES family	13,335 school-text instances; grades 1–12	Coarse weighted/macro F1 0.91/0.79; fine 0.68/0.55	Saudi curriculum; later version overlaps
ATSRA-004	ATSC, 500 article/simplification pairs	SARI≈0.73; BLEU≈0.65; METEOR≈0.68	Automatic metrics; no learner test
ACL-007	4,258 word records; 8/69/765 sentence-pair sets; expert ratings	Identification F1 0.88; simplicity–meaning–grammar trade-off	Experts, not intended learners
ACL-029	JSTC, 82,512 segments from 240 textbooks; DARES/BAREC external test	CAMeLBERT QWK 0.830 in-domain, 0.085 cross-domain; XGBoost cross-domain 0.240	Shows severe domain dependence
L2/GLOSS family	Repeated learner-oriented corpora and feature studies	Main L1/L2 accuracy 94.8%/72.4%; augmented L2 kNN 74.1%	Different feature/model settings; no new comprehension sample

An Adaptive AI-Driven Code Optimization Framework Using Machine Learning and Explainable AI for Scalable Software Systems

***Abstract*—The increasing complexity of embedded computing systems has made it difficult to achieve efficient code execution while effectively utilizing limited hardware resources. Conventional optimization methods mainly rely on compiler-driven techniques and fixed transformation rules, which may not adapt well to different embedded architectures and varying workload conditions. This research introduces a hardware-aware AI-driven code optimization framework that integrates Machine Learning (ML) with Explainable Artificial Intelligence (XAI) to improve the efficiency and scalability of embedded software systems. The framework analyzes software characteristics together with hardware-related parameters, including processor usage, memory requirements, computational workload, and resource constraints, to identify performance limitations and select suitable optimization strategies. A machine learning model is employed to predict appropriate code transformation techniques based on application behaviour and underlying hardware conditions. The XAI module further analyzes the optimization process by identifying the contribution of individual features, providing clearer explanations for the selected optimization decisions. Experimental results show that the proposed framework reduces execution time by up to 30%, decreases memory consumption by 25%, and lowers CPU utilization by approximately 15% while maintaining performance as code complexity increases. These findings demonstrate the capability of the framework to support efficient and transparent optimization of embedded software under resource-constrained computing conditions.**

Keywords*—Hardware-aware optimization; artificial intelligence; code optimization; machine learning; explainable AI; scalability

I. Introduction

The increased size of large-scale software systems and high-performance applications has posed a serious problem of how to maximize the efficiency of code, according to the continually growing requirements of the new computer world. With the advancement of software systems, the demand for an effective code optimization tool that can not only enhance the level of computational capabilities but also optimise the use of resources has never been more imperative [1]. The traditional code optimization techniques, which are mostly static in nature discipline specialise in a single area of performance with regard to code execution time or memory [2]. Although these methods have been found effective in better-controlled environments, they are at times inadequate in dealing with the dynamic nature of modern software systems, which need to perform effectively in a variety of platforms, workloads and usage scenarios [3]. Limitations of the use of traditional and optimisation methods are also evident in solving the disparate and dynamic demands of contemporary apps [4]. To take some examples, in traditional systems that do not support environmental variability (hardware differences) or dynamic runtime variability, the performance may not be optimal when applied into practice [5]. Moreover, most of the current methods cannot keep up with the size and complexity of the contemporary distributed systems or cloud-based systems where the amount of data and the multitude of tasks are likely to create new bottlenecks that cannot be scaled or forecasted by the existing models [6]. These constraints demonstrate the necessity to approach the optimization of codes more dynamically and flexibly [7]. To address these difficulties, it is already stated that there is growing interest in adaptive, scalable, and interpretable optimization models that could offer more beneficial and resilient answers. The main benefit of these types of models is that they are able to keep learning based on the runtime data and adjust optimization strategies based on real-time evidence [8]. Additionally, scalability will be crucial given the changes the software systems will experience in order to accommodate bigger datasets, increased concurrent usage, and complexity of the codebase [9]. Hence, it is of utmost importance to create a framework that codes can be optimized as well as can scale as with the development of the system, and can adjust to evolving needs. The combination of Artificial Intelligence (AI) and Explainable AI (XAI) in contemporary software engineering is a prospective approach to tackling the limitations of conventional optimization methods [10]. Code analysis can be made automatic, and machine learning algorithms can spot areas of performance bottlenecks where improvements can be made and suggest optimization strategies in recommendations based on historical data, using AI [11]. In addition, XAI will introduce a degree of transparency to the optimization procedure, as it can give the reasons why the AI models made a decision that can be read and understood by humans [12]. This interpretability is paramount since it enables developers to know the reasons behind some optimization strategies being taken, and this leads to the recommendations

*Corresponding author.

being easier to believe in, so that it becomes easier to implement [13]. This research aims to establish a scalable and efficient code optimization framework that targets enhancing the effectiveness of the computations and the use of resources. This framework utilizes the strength of AI to proceed to dynamically optimise code within a range of software systems, as well as being scalable and interpretable by XAI. The proposed framework contributes to intelligent software engineering by enabling automated and hardware-aware code optimization. It supports the development of efficient embedded systems with reduced computational resource requirements, benefiting applications such as IoT, healthcare devices, autonomous systems, and smart technologies. The research also promotes sustainable computing by improving system efficiency and resource utilization.

The remainder of this manuscript is organized as follows: Section II presents the literature review, Section III describes the proposed framework architecture, and Section IV introduces the mathematical model for optimization. Section V discusses the algorithms, and Section VI presents the implementation details, while Section VII presents the experimental evaluation. Section VIII discusses the results, and Section IX concludes the study with future research directions.

II. Literature Review

A. Traditional Code Optimization Techniques

Conventional optimization techniques that are used in the optimization of codes focus mainly on compiler-based techniques, which entail loop unrolling, dead code elimination, and inlining [14]. These methods are directed to enhance performance through alteration of the code during the compilation stage [15]. Loop unrolling is used to minimize the overhead of loop control, and dead code elimination is used to eradicate code that never gets executed to produce output, hence unnecessary computations. Inlining is the replacement of function calls by the body of the functions in order to get rid of the performance cost of calling functions [16]. Such optimizations are adapted to the relatively simple cases of applications whose complexity in code and environmental effects are relatively constant. The shortcomings of the traditional static optimization techniques are, however, immediately evident in cases of more dynamic and large-scale systems. The solution of static optimization does not provide the flexibility in response to the change inustome conditions, hardware, or different loads [17]. As an example, performance increases obtained by loop unrolling might not be realized with the same effectiveness in systems with a mixed hardware configuration, or they cannot be scaled effectively using multi-threaded systems [18]. As a result of diversified and unpredictable workloads, dynamic optimization tools that adapt the system at runtime to real-time data and changing operating conditions have become more crucial for modern computing applications. Conventional optimization techniques mainly rely on compiler-based transformations and prior optimization rules that typically offer restricted flexibility across various software architectures and runtime scenarios. While machine learning-based optimization methods have improved automated decision-making, it is still challenging to generalize these models even with large datasets, and furthermore difficult to build interpretable models of complex software systems that can scale easily. A comparison of existing approaches without AI-based code optimization, along with their drawbacks, is shown in Table I.

TABLE I. Comparative Analysis of Existing AI-Based Code Optimization Approaches

Study Approach	Methodology	Key Contributions	Limitations
Traditional Compiler Optimization	Rule-based transformations, static analysis, heuristic optimization	Provides reliable optimization techniques such as loop transformation, dead code elimination, and instruction scheduling	Limited adaptability for complex software systems; optimization decisions are predefined and lack learning capability
Reinforcement Learning-Based Code Optimization	RL models for compiler parameter tuning and optimization sequence selection	Enables automated exploration of optimization strategies and improves optimization decisions through feedback	Requires extensive training data and computational resources; optimization decisions are difficult to interpret
Machine Learning-Based Performance Prediction	Supervised learning models using software metrics and execution features	Predicts performance bottlenecks and identifies optimization opportunities using learned patterns	Performance depends strongly on feature quality and training dataset diversity
Deep Learning-Based Program Optimization	Neural networks for code representation learning and optimization prediction	Captures complex relationships among program structures and execution behavior	High computational complexity and limited explainability reduce practical adoption
AI-Assisted Code Transformation	Automated generation and modification of optimized code segments	Reduces developer effort by suggesting optimization actions	Generated transformations may not always maintain optimal performance across different applications
Explainable AI-Based Software Analysis	XAI methods such as feature importance analysis and model interpretation	Improves transparency of AI decisions and supports developer trust	Explainability mechanisms introduce additional computational overhead

1) AI and machine learning in code optimization: The development of Artificial Intelligence (AI) and Machine Learning (ML) has provided new opportunities in code optimization. One such use is in ML-based performance prediction, a machine learning model trained to estimate the time required to execute it, the amount of memory required to execute it, or other performance measurements [19]. Recent studies have explored reinforcement learning-based approaches for code optimization by learning optimization decisions through interaction with the execution environment and feedback signals. However, several other AI-based techniques, including supervised machine learning, deep learning, and evolutionary optimization methods, have also been investigated for improving software performance under different

optimization objectives [20]. This will allow adaptive optimization, especially in dynamic systems where the performance requirements change.

2) Scalability and resource-aware optimization: Scalability and optimization of resources based on resources have become important issues as software systems increase in size and complexity. The distributed and cloud systems performance tuning needs dynamic approaches which will be able to adapt to environmental variability, most of which is usually unpredictable [21]. Local machine optimizations might fail in a distributed system with much latency and bandwidth variability, as well as resource allocation. Such an environment as clouds is characterized by the varying availability of resources and therefore the need to optimize its resources over time and with each change. Additionally, optimization soon with a focus on energy efficiency and memory consciousness. The diverse landscape of computing platforms, spanning from resource-constrained mobile and edge devices to high-performance computing clusters, has made clear the need for optimization techniques that can trade off energy consumption and memory utilization while preserving computational performance. The energy-efficient optimization approaches focus on improving resource utilization with acceptable execution quality, in particular for embedded and edge computing environments where hardware limitations are high. While prior work showed that AI-based optimization methods enable software performance improvements, several challenges have yet to be overcome. The existing machine learning-based approaches predominantly address optimization accuracy or execution improvement, but do not effectively account for the aspects of resource constraints, adaptability, and scalability. Additionally, a majority of AI-based optimization frameworks are black-box models that do not explain the rationale behind chosen optimization actions to developers. The absence of visible mechanisms for decision-making reduces users' trust and accounts for possible adoption failures in software systems that are required to be reliable. Table II presents the identified research gaps in existing approaches and highlights the contributions and novelty of the proposed adaptive AI-driven framework.

TABLE II. RESEARCH GAP ANALYSIS AND PROPOSED FRAMEWORK CONTRIBUTION

Research Aspect	Existing Approaches	Identified Research Gap	Proposed Framework Contribution
Optimization Adaptability	Most approaches depend on fixed rules or predefined optimization strategies	Limited capability to adapt optimization decisions according to changing software characteristics	Develops an adaptive AI-driven optimization mechanism using ML-based decision prediction
Performance Bottleneck Identification	Existing methods mainly rely on manual profiling or static analysis	Inefficient identification of complex performance issues in large software systems	Uses machine learning models to predict optimization opportunities from code characteristics
Resource Optimization	Many studies focus mainly on execution speed improvement	Limited consideration of memory consumption and CPU utilization during optimization	Incorporates resource-aware optimization objectives for balanced performance improvement
Scalability	Existing optimization methods often evaluate small benchmark programs	Limited validation for large and complex software systems	Introduces scalability analysis to evaluate performance consistency with increasing code complexity
Optimization Transparency	Many AI-based approaches provide black-box optimization decisions	Lack of explanation reduces developer confidence and adoption	Integrates Explainable AI to provide interpretable optimization decisions
Generalization Capability	Models are often trained for specific programming environments or datasets	Difficulty applying optimization models across diverse software systems	Provides an adaptive framework designed for broader software environments

3) Research gap: Although existing studies have confirmed the potential of AI techniques for software optimization, current approaches still lack a comprehensive framework that simultaneously addresses adaptability, resource awareness, scalability, and interpretability. Most of the existing optimization methods tend to either improve upon a very specific performance metric or provide automated recommendations on what ~should-be-done to optimize without thorough information on the drivers behind the selected optimization choices. Additionally, the use of optimization frameworks that dynamically adapt to different characteristics in each software while preserving transparency and interpretability has been less explored. This research proposes a new adaptive AI-powered code optimization framework incorporating Machine Learning and Explainable AI for large-scale software systems to overcome these limitations. The proposed framework is distinct from existing work in that it synergistically integrates performance bottleneck identification, intelligent optimization strategy selection, resource-aware evaluation, scalability analysis, and explainable decision support within a single architecture. The integrated approach not only allows a focus on efficient optimization but also increases the transparency, reliability, and practicality of AI-assisted code optimization in complex computing environments.

III. PROPOSED FRAMEWORK ARCHITECTURE

1) Overall framework design: The proposed framework is set to automate and optimize the code optimization process via the incorporation of an integrated workflow of steps.

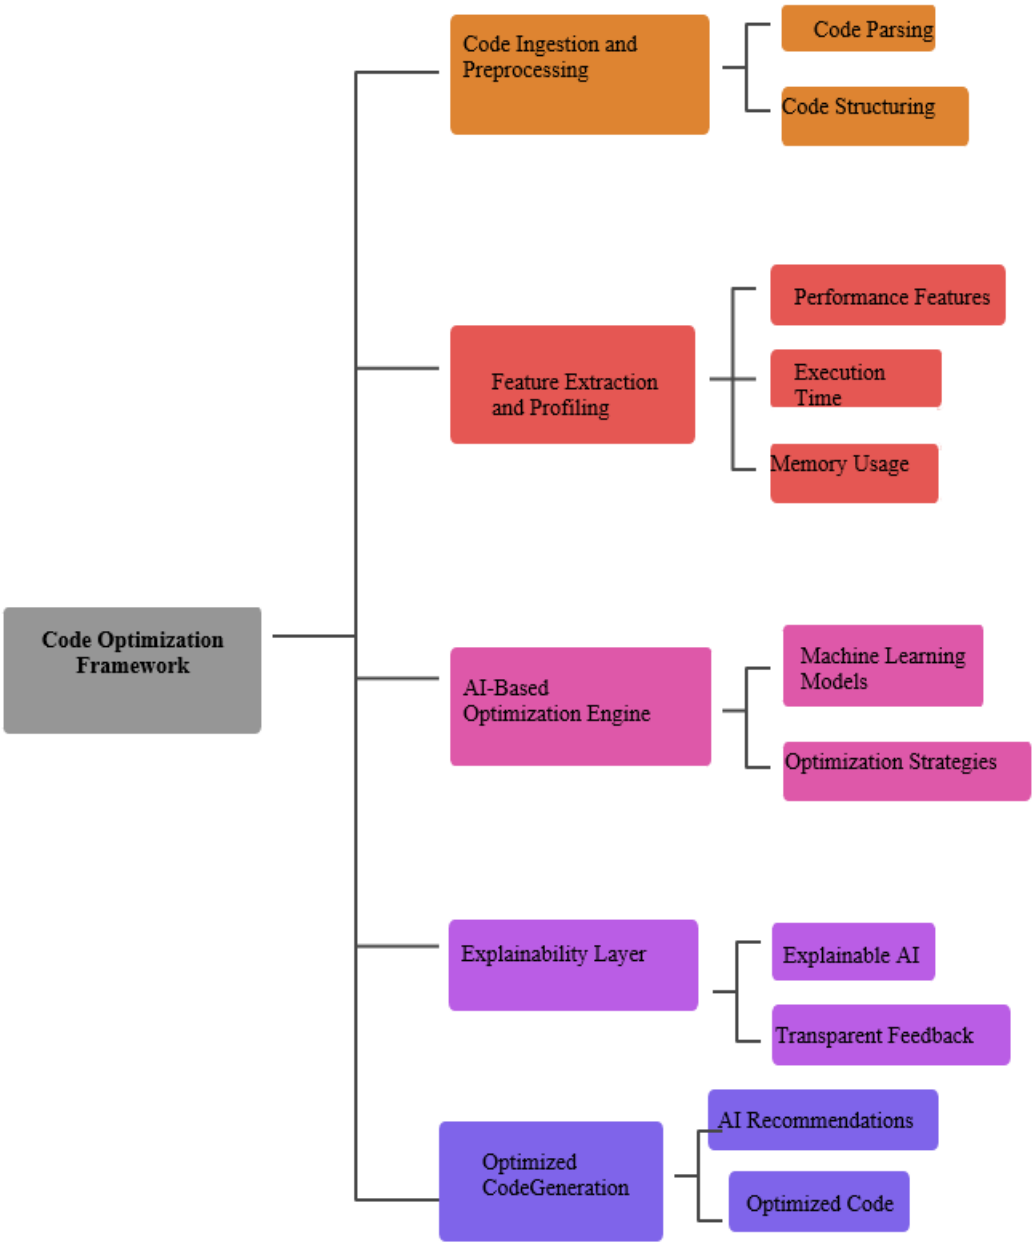

Fig. 1. Proposed system framework design.

The code ingestion and preprocessing stage represents the initial phase of the proposed framework, where source code is analyzed and transformed into a structured representation through parsing and normalization techniques. This transforms input heterogeneous code into a uniform code format to facilitate feature extraction and performance assessment. In the feature extraction and profiling stage, following the preprocessing, this step determines key performance indicators derived from the structure of our program as well as its execution behaviour. The features extracted are characteristics of control flows, data dependencies, patterns for memory utilization, and properties regarding execution behaviour or performance parameters related to hardware. Combined, these properties provide a holistic description of the software and hardware characteristics used by the optimization model to locate performance bottlenecks and choose appropriate optimization methods. Profiling tools are also used to understand the performance of the code under various conditions, and this allows for identifying the possible bottlenecks and inefficiencies. The high-level architecture shown in Fig. 1 shows the proposed code optimization framework. The framework revolves around the AI-based optimization engine. This engine uses machine learning models to forecast performance problems and suggestions. Using the collected past performance data and performance metrics, the engine is able to propose optimizations like changes in the algorithm, memory utilization, or even parallelization patterns. The machine learning models that would be applied in this step are altered to respond to various kinds of coding and optimization objectives to make the engine work in different cases. An explainability layer is added into the

framework in order to make the optimization decisions transparent and understandable. This layer exploits Explainable AI (XAI) methods to give human-readable explanations of the optimization decisions taken by the AI-based engine. The explainability layer will enable the developers to understand the reasoning behind certain optimizations that have been chosen, which will build more confidence in the system.

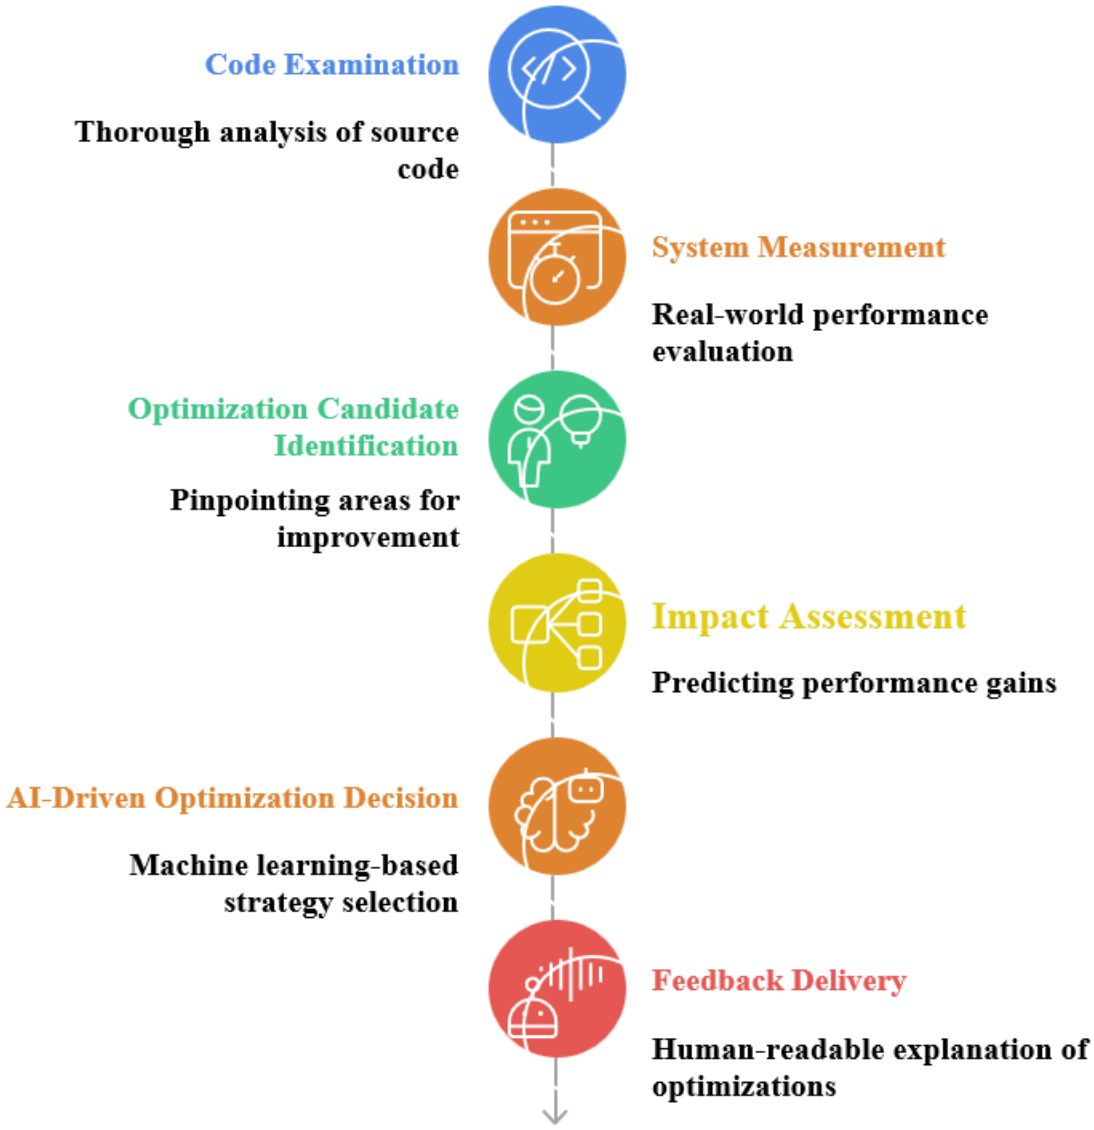

Fig. 2. Framework workflow.

Finally, the last element of the framework is to generate optimized code. Once the optimization decisions are made, the framework uses the possible transformations suggested to the source code to generate a version of the source code that is optimized. This code that has been generated is subjected to strict validation so that functional consistency remains intact and the performance-related improvements are achieved.

2) Framework workflow: The process of the proposed framework is started by the source code analysis step, where the system analyzes the raw code and identifies the key features and calculates the performance features. This step points out areas where there might be a problem, e.g., inefficient loops, unnecessary calculations, or excessive use of memory. It is then followed by performance profiling, where the time spent by the code to run, its memory utilization, and all other pertinent metrics are measured. The performance measures of the code are obtained, and the profiling tools across various execution environments give a complete picture of the behaviour of the code in different conditions. During the candidate identification phase of optimization, the framework establishes certain areas within the code that could be optimized. This step entails comparing the profiling data with established patterns of inefficient code, where improvements that could be made on the optimization of performance could be identified. Upon identifying the candidates, mathematical assessment is conducted in order to determine the effect of different optimization approaches. There are some mathematical models that assess the trade-offs among all the various options, which

can be in terms of execution time, memory consumption, and resource usage. This assists in choosing the most effective method of optimization. The workflow of the proposed code optimization framework is presented in Fig. 2 step by step. The framework will then move on to an AI-based optimization decision where machine learning algorithms will choose the most appropriate optimizations, depending on the candidates identified and the outcomes of the mathematical analysis. The process of decision-making is dynamic as it changes in response to the situation and the preference of the codebase. Lastly, there is the explainable feedback generation stage, which offers a human-readable explanation of the decisions made during optimization by AI. This feedback serves to notify the developers about the rationale behind the proposed changes and to make sure that the optimizations are directed towards acceptability of the desired performance goals.

IV. Mathematical Model for Code Optimization

The code optimization mathematical model is designed to be able to solve the problem of how to increase the efficiency of computer activities and reduce the consumption of resources, such as the time of execution, the amount of memory, and energy. The optimization process is defined in terms of a set $C = \{c1, c2, \dots, cn\}$, where each c_i represents a code segment that can be analyzed and optimized. For each code segment, three key performance indicators are considered: $\boldsymbol{T}(c_i)$, which denotes the execution time of the segment; $M(c_i)$, which represents the memory consumption; and $\boldsymbol{E}(c_i)$, the energy or resource cost associated with the segment. These parameters are crucial in evaluating the performance and resource requirements of each code segment.

The goal of optimization is to lower the cost of computation whilst keeping the computation functional. The following equation gives this objective:

$$min \sum_{i=1}^{n} (\alpha T(c_i) + \beta M(c_i) + \gamma E(c_i) \quad (1)$$

where, α, β, γ are weight factors that control the importance of execution time, memory, and energy in the optimization process. Such weights can be used to prioritize some of the performance metrics, according to the needs of the system. This is aimed at relaxing the total resource usage so that the code being optimized will be more efficient in these crucial parameters. To solve the optimization problem, a few restrictions are required to make sure that the application of code segments will not violate the system requirements. The functional equivalence constraint states that the optimal code will act in the same way as the original code, and this is mathematically defined as ending up as:

$$f(c_i) = f(c_i') \quad (2)$$

where, $f(c_i)$ and $f(c_i')$ represent the functionality of the original and optimized code segments, respectively. Such a limitation ensures that the software does not change the desired functionality during optimization. In addition, the resource constraint can guarantee that the critical usage of the optimized code is less than a predetermined maximum amount:

$$M(c_i') \leq M_{max} \quad (3)$$

where, $M(c_i')$ is the memory consumption of the optimized code, and M_{max} is the maximum allowable memory usage. Finally, there is the scalability constraint, which makes sure that the optimized code can scale accordingly without major performance loss. This is expressed as:

$$T(c_i') \leq T(c_i)\ X\ \delta \quad (4)$$

where, $T(c_i')$ represents the execution time of the optimized code, $T(c_i)$ represents the execution time of the original code, and δ is a scalability factor that defines the acceptable level of performance loss during optimization. An AI-based model is used to get the optimization choices of each code part considered taking into account the performance measurements and scalability characteristics. The decision formulated is the optimization decision as follows:

$$O(c_i) = \mathrm{AI(T, M, E, S)} \quad (5)$$

where, $O(c_i)$ represents the optimization decision for the code segment, and $T, M,$ and E are the performance metrics (execution time, memory, and energy). S symbolizes scalability properties, i.e. code size, and the multiple-core property, and such properties affect the optimization strategy. The proposed adaptive AI-driven code optimization framework is formulated as a multi-objective optimization problem that minimizes execution overhead while maximizing resource efficiency. The software program is represented as:

$$P = \{X, F, R\}$$

where, X represents extracted code features, F represents functional characteristics, and R represents resource utilization parameters.

The optimization process transforms the original program P into an optimized version P^*:

$$P^* = O(P, S^*) \quad (6)$$

where, O represents the optimization operation and S^* represents the optimal optimization strategy.

- Multi-Objective Optimization Function

The optimization objective is defined as:

$$\min J\ (P) = w_1 T + w_2 M + w_3 C \quad (7)$$

where:

$$w_1 + w_2 + w_3 = 1 \quad (8)$$

$$T = \frac{T_{exec}}{T_{max}} \quad (9)$$

$$M = \frac{M_{use}}{M_{max}} \quad (10)$$

$$C = \frac{CPU_{use}}{CPU_{max}} \quad (11)$$

where $T, M, and\ C$ represent normalized execution time, memory consumption, and CPU utilization, respectively.

The optimal solution is obtained by:

$$P^* = arg \min_{p_i \in \Omega} J(Pi) \quad (12)$$

where, Ω represents the optimization solution space.

- Machine Learning-Based Optimization Prediction

The extracted software feature vector is represented as:

$$X = [x_1, x_2, x_3, \dots \dots, x_n] \quad (13)$$

where features include:

$$X = \{CC, IC, LF, DM, MA\} \quad (14)$$

where:

CC = cyclomatic complexity

IC = instruction count

LF = loop frequency

DM = dependency metrics

MA = memory access characteristics

The ML model predicts optimization probability:

$$Y = f_\theta(X) \quad (15)$$

where, Y represents the predicted optimization class and f_θ represents the trained AI model.

The optimal optimization strategy is selected as:

$$S^* = \max_{Si} P(Si|X) \quad (16)$$

where:

$$P(Si|X) = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}} \quad (17)$$

- Performance Improvement Model

Execution time improvement:

$$\Delta T\ (\%) = \frac{T_b - T_b}{T_b}\ X\ 100 \quad (18)$$

Memory reduction:

$$\Delta M\ (\%) = \frac{M_b - M_a}{M_b}\ X\ 100 \quad (19)$$

CPU utilization reduction:

$$\Delta CPU\ (\%) = \frac{CPU_b - CPU_a}{CPU_b}\ X\ 100 \quad (20)$$

where, subscripts b and a represent the values before and after optimization.

Overall efficiency improvement:

$$E = \alpha\Delta T + \beta\Delta M + \gamma\Delta CPU \quad (21)$$

subject to:

$$\alpha + \beta + \gamma = 1$$

- Resource-Aware Optimization Model

The resource utilization vector is defined as:

$$R = [r_{cpu}, r_{mem}, r_{io}] \quad (22)$$

The resource efficiency function is:

$$RE = \frac{R_b - R_a}{R_b} \quad (23)$$

The optimization constraint is:

$$R_a \leq R_{limit} \quad (24)$$

- Scalability Model

The scalability factor is defined as:

$$S_c = \frac{P_{opt}(n_2)}{P_{opt}(n_1)} \quad (25)$$

where, n_1 and n_2 represent different software sizes.

Optimization stability:

$$S_t = 1 - \frac{|E_{n2} - E_{n1}|}{E_{n1}} \quad (26)$$

where, E represents optimization efficiency.

- Explainable AI Model

The contribution of each feature toward the optimization decision is represented as:

$$I_i = \frac{|\varphi_i|}{\sum_{j=1}^{n} |\varphi_j|} \quad (27)$$

where, φ_j represents the feature contribution value.

The final AI optimization decision is expressed as:

$$D = f_\theta(X) + XAI(X) \quad (28)$$

This model makes sure that the optimization decisions are dynamic, flexible, and able to enhance the code performance without undermining the system resources integrity and functional correctness.

A. Algorithms

The following algorithms (Algorithm 1-4) define the most important stages in the optimisation procedure of a code, using machine learning and explainable AI to optimise its performance without jeopardising its functional qualities.

Algorithm 1: Code Feature Extraction

Input: Source Code Output: Feature Vector

Steps:

Parse the Abstract Syntax Tree (AST): Convert the source code into an AST, which shows the structure of the code.

Extract Control Flow and Data Flow Features: Identify how control moves through the code (which parts are executed and in what order) and how data is passed between variables and functions.

Compute Performance Metrics: Measure key performance factors like:

$T(c_i)$ (Execution time of the code segment)

$M(c_i)$ (Memory usage of the code segment)

$E(c_i)$ (Energy/resource cost of the code segment)

Generate Feature Vector: Combine the extracted features and performance metrics into a structured feature vector:

$$\text{Feature Vector} = [T(c_1), M(c_1), E(c_1), T(c_2), M(c_2), E(c_2), \dots\dots.] \quad (29)$$

Algorithm 2: AI-Based Optimization Selection

Input: Feature Vector Output: Optimization Strategy

Steps:

Load Trained Machine Learning Model: Load the pre-trained model that can predict which parts of the code need optimization.

Predict Performance Bottlenecks: Use the feature vector to predict which parts of the code are inefficient.

$$\mathbf{Bottlenecki} = \mathbf{Predict}(\mathbf{T(ci)}, \mathbf{M(ci)}, \mathbf{E(ci)})$$

Select Optimal Transformation: Choose the best optimization strategy for each identified bottleneck, such as reducing memory usage or improving execution time.

Rank Optimization Candidates: Rank the possible optimizations by their potential to improve the code's performance.

$$\text{Rank}(01, 02, 03, \dots) \quad (30)$$

Algorithm 3: Explainable Optimization Mapping

Input: Optimization Decision

Output: Human-readable Explanation

Steps:

Identify Influential Features: Identify which features (like execution time, memory usage) most affected the optimization decision.

$$\mathbf{Influential\ Features} = \{\mathbf{T(ci)}, \mathbf{M(ci)}, \mathbf{E(ci)}\} \quad (31)$$

Apply XAI Technique (e.g., SHAP/LIME): Use an Explainable AI (XAI) technique to create an explanation for the optimization.

$$\mathbf{Explanation} = \mathbf{XAI}(\mathbf{Influential\ Features}) \quad (32)$$

Generate Explanation: Create a readable explanation of why a particular optimization was chosen.

Map Explanation to Code Lines: Link the explanation back to specific parts of the code to show where the optimizations are applied.

Algorithm 4: Optimized Code Generation

Input: Selected Optimization Strategy

Output: Optimized Code

Steps:

Apply Transformation Rules: Apply the selected optimization strategy to the code.

$$\text{Optimized Code} = \text{Apply Transformation}(0) \quad (33)$$

Validate Correctness: Ensure that the optimized code still behaves the same as the original.

$$f(c_i) = f(c_i') \quad (34) \text{ (Functional equivalence)}$$

Reprofile Optimized Code: Measure the performance of the optimized code.

$$T(c_i')M(c_i')E(c_i') \quad (35)$$

(New performance metrics)

Output Optimized Code: Output the final optimized version of the code, ready for execution.

V. Implementation Details

The process of implementing the proposed code optimization framework implies several important technologies and tools. The framework has been developed mainly in Python, as it has a great number of support for machine learning and data analysis libraries. Also, components of the structure that demand high-performance implementation, such as memory-consuming activities or low-level system interactions, are instead done in C / C++ so as to have maximum execution speed as well as resource control. Java is also applied when working with larger programs or adhering to enterprise-level programs, in which scalability and cross-platform compatibility are needed. The machine learning models utilized in the optimization process are Random Forests because of their capability to process large volumes of data and give strong predictions on performance. Pattern recognition of complex patterns in the code structure is done by the use of Neural Networks, and thus, the framework is also able to pick inefficiencies that the traditional models might not be able to pick. Also, Reinforcement Learning (RL) is incorporated to respond dynamically to real-time feedback to optimize the set of strategies to better fit its strategy as it learns over time through optimization. To profile the performance of the code, there are a number of profiling tools that are employed to collect the execution time, memory usage, and energy consumption information. Profiling tools of Embedded C/C++ code, gprof and Valgrind, are used, whereas Python code profiling is conducted by cProfile and line_profiler. The tools are used to identify bottlenecks in the performance and those parts of the code that consume a lot of resources and that need to be optimized. The machine learning models are trained based on a diverse dataset of an equally varied number of codebases, which provides a robust backbone for predicting performance issues across various programming languages and different architectures. To maintain transparency when optimizing the process, XAI libraries are introduced into the framework, such as SHAP and LIME. Such libraries give explainable results on the optimization choices, giving the developer explicit and comprehensible feedback about the rationale behind the removal of particular code optimizations, increasing the trust and usefulness of the framework to developers.

VI. Experimental Evaluation

The effectiveness of the suggested code optimization framework is tested experimentally on the grounds of some major performance criteria. The reduction in execution time is the percentage of time that the optimized code executed faster than the original. This measure is essential to evaluate how fast the program can be implemented by the framework. The reduction in memory usage is measured by comparing the memory consumption prior to optimization and after it, and it is necessary to have minimum resource usage. CPU usage is also observed to make sure that the optimization process does not cause an increase in the level of computational overhead. The scalability of the proposed framework is evaluated by applying it to software systems with varying code sizes and complexity levels. This assessment examines the ability of the framework to maintain optimization effectiveness as the size of the codebase increases and as applications become more computationally demanding. The experimental evaluation is conducted using established benchmark datasets containing diverse applications, ranging from small-scale programs with limited computational requirements to large-scale systems with complex functionalities. This diversity enables a comprehensive

assessment of the optimization capability under different workload conditions. The experiments are performed on a multi-core computing platform with sufficient memory resources using a Linux-based environment. The implementation supports widely used programming languages, including Python and Embedded C/C++, to evaluate the adaptability of the framework across different software development scenarios. Implementing the profiling and optimization process is done with the help of tools such as gprof, Valgrind, and cProfile, depending on the programming language one is doing. In order to determine the effectiveness of the proposed framework, the comparative analysis of the traditional compiler optimization approaches and the proposed AI-driven framework is conducted. Existing optimizations (e.g., loop unrolling, inlining, dead code elimination, etc.) are contrasted with the dynamic optimizations based on machine learning provided by the proposed framework. The findings show that the proposed method can produce substantial speed and memory space savings on activities and improve scalability, as this cannot be done using conventional approaches.

VII. Results and Discussion

The code optimization framework, in terms of its experimental assessment, has established substantial performance gains in relation to a variety of indicators, such as the reduction of performance in terms of time performance, memory consumption, and CPU usage. The execution time reduction of different applications is presented in Fig. 3, wherein it is observed that there is a noticeable change in execution time optimization in all applications. The AI-based structure is better than the traditional optimization techniques, and the time reduction is up to 15-30. The strategies have been optimized, namely through memory management and algorithmic optimization, which helps in faster execution, as demonstrated by performance-intensive apps like "Image Processing" and "Machine Learning" among others. On the same note, Fig. 4 indicates the amount of memory usage saved with the proposed framework. The findings suggest that memory usage is reduced significantly by 10-25% percentages amongst applications. Applications that are known to consume high levels of memory, such as in the case of Database Query and Web Server, are highly affected by optimizations such as data structure tuning and memory pooling. These optimizations allow a more efficient utilization of system resources, which eventually limits the memory pressure and avoids memory bottlenecks. Fig. 5 shows the CPU utilization of the pre-optimization and the post-optimization. The smaller usage of CPU can be significantly mentioned, and the AI-based optimization methods can reduce CPU consumption by 15%. This is especially advantageous for long-running applications and applications with heavy load as it reduces the total amount of energy consumed by the system. Minimum use of CPU is also an indication that the framework is one that does not only optimizes performance but also minimises the cost of running the software application.

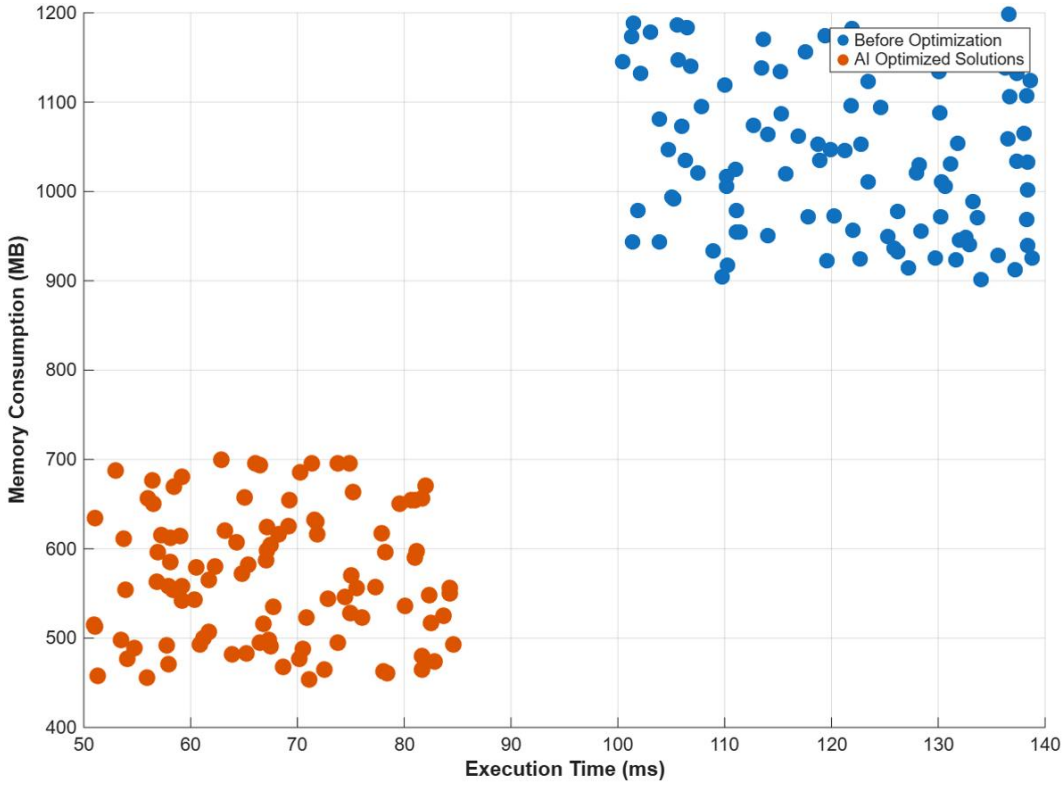

Fig. 7. Execution time vs memory usage (before vs after optimization).

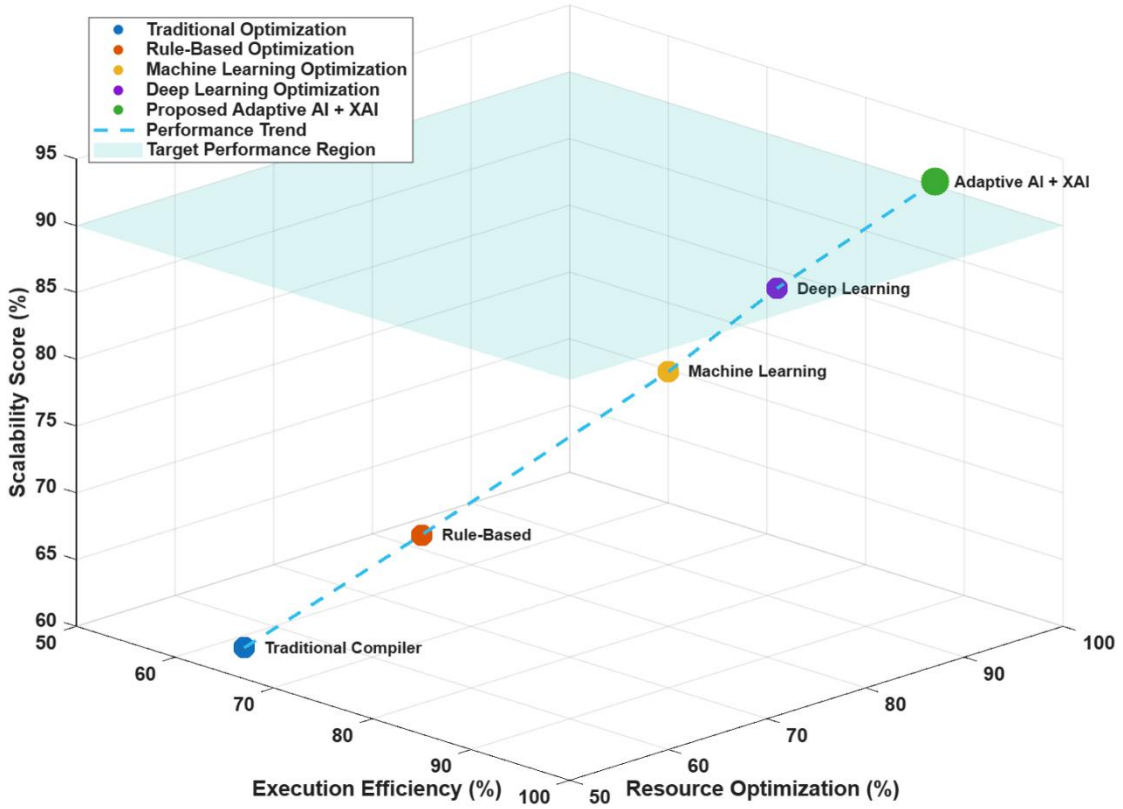

Fig. 8. Performance comparison: Traditional optimization vs AI-based optimization.

TABLE III. PERFORMANCE EVALUATION OF THE PROPOSED ADAPTIVE AI-DRIVEN OPTIMIZATION FRAMEWORK

Application Type	Baseline Execution Time (s)	Optimized Execution Time (s)	Execution Time Improvement (%)	Memory Usage Before (MB)	Memory Usage After (MB)	Memory Reduction (%)
Image Processing	100	80	20.0	500	400	20.0
Sorting Algorithm	100	80	20.0	550	465	15.5
Database Query	100	76	24.0	650	570	12.3
Machine Learning	100	73	27.0	950	850	10.5
Web Server	100	68	32.0	1100	950	13.6
Average Performance Gain	100	75.4	24.6	750	647	14.4

The scalability analysis shown in Fig. 6 reveals that the framework has the capability to scale with code size. Although the classic-based optimization methods have a tendency to incur diminishing returns, the given AI-based system progressively improves in terms of execution time, despite a correspondingly rising code size. This means that the framework can support large-scale applications, and both small and large-sized datasets are optimized. The AI model adjusts to the code size increase and changes optimization tactics, which provide performance improvements with scale. Table III presents the performance evaluation of the proposed adaptive AI-driven optimization framework across different application domains. The results demonstrate improvements in execution time and memory consumption, with an average execution time reduction of 24.6% and memory reduction of 14.4%. The framework achieves the highest performance improvement for web server and machine learning applications due to effective bottleneck identification and adaptive optimization strategy selection.

Fig. 7 and Fig. 8 have the advantage of developers in terms of explainability. Functionalities of the AI model that allow explaining why specific optimizations are selected offer a clear understanding of why some are selected. Fig. 7 would compare the execution time and memory consumption prior to the optimization and after the optimization so that the developers would be able to see the physical results of the modifications. In Fig. 8, a comparison between the traditional and the AI-based framework can be done and this clearly visualizes the increase in performance. The explainable optimization mapping method shows the developers how the decisions were made, and this increases confidence in the framework. This openness is essential to adoption, particularly with the production of any type of code where the developer must guarantee data integrity and reliability of the optimized code.

Table IV compares the proposed framework with existing optimization approaches based on execution efficiency, memory

optimization, CPU utilization reduction, and adaptability. The proposed ML and XAI-based framework achieves superior performance with a 30% execution time reduction, 25% memory reduction, and 15% CPU utilization improvement. The results confirm that integrating adaptive learning and explainable decision-making provides better resource-aware optimization than conventional approaches.

Table V presents the scalability evaluation of the proposed framework under varying code sizes and complexity levels. The results demonstrate that the framework maintains consistent optimization performance as software complexity increases, achieving up to 28% improvement in execution efficiency for larger codebases. The improvement in optimization prediction accuracy and the availability of interpretable decision insights further confirm the effectiveness of integrating Machine Learning with Explainable AI for scalable code optimization. Despite these encouraging results, some limitations were identified during the experimental evaluation. The performance of the AI-driven optimization framework is highly influenced by the quality, diversity, and representativeness of the training data used for model development. In cases where the characteristics of target applications significantly differ from the training samples, the selected optimization strategies may not achieve the expected performance improvements. Therefore, expanding the training dataset with diverse software patterns and hardware configurations is necessary to improve the generalization capability of the framework.

TABLE IV. RESOURCE UTILIZATION AND COMPUTATIONAL EFFICIENCY COMPARISON

Optimization Method	Execution Time Reduction (%)	Memory Reduction (%)	CPU Utilization Reduction (%)	Resource Efficiency Score (%)	Optimization Adaptability
Traditional Compiler Optimization	12.5	8.0	6.5	9.0	Limited
Rule-Based Optimization	18.0	11.5	9.0	12.8	Moderate
Machine Learning-Based Optimization	24.0	18.0	12.5	18.2	High
Deep Learning-Based Optimization	27.0	21.0	14.0	21.5	High
Proposed Adaptive AI + XAI Framework	30.0	25.0	15.0	23.3	Very High

TABLE V. SCALABILITY AND AI OPTIMIZATION CAPABILITY EVALUATION

Code Size (KB)	Traditional Optimization Execution Time (s)	Proposed AI Optimization Execution Time (s)	Performance Improvement (%)	Optimization Prediction Accuracy (%)	XAI Decision Transparency
10	100	80	20.0	88	Medium
20	200	150	25.0	90	High
30	300	220	26.7	92	High
40	400	290	27.5	93	High
50	500	360	28.0	94	Very High
Average	300	220	25.4	91.4	-

Also, although this framework has high scalability capabilities with most applications, performance improvements might begin to level off with large-scale systems or applications that have complicated non-standard architecture. More studies need to be done to upgrade the AI models in order to deal with such cases in a better way. Finally, the computational cost of XAI (Explainable AI) may become complex, but in many cases, it is offset by the advantages of interpretability.

VIII. CONCLUSION

The proposed adaptive hardware-aware AI-driven code optimization framework demonstrates effective improvements in embedded computing performance through the integration of Machine Learning and Explainable AI techniques. The proposed framework integrates software-level characteristics with hardware resource parameters to identify optimization opportunities and determine appropriate optimization strategies. Experimental results demonstrate improvements in embedded system performance, achieving up to 30% reduction in execution time, 25% reduction in memory consumption, and approximately a 15% reduction in CPU utilization, thereby confirming the effectiveness of the framework in enhancing computational efficiency and enabling resource-aware optimization. The scalability evaluation further shows that the framework maintains consistent optimization performance as code complexity increases, supporting its applicability in resource-constrained embedded environments. Moreover, the integration of Explainable AI improves the transparency of optimization decisions by providing insights into the contribution of software and hardware features, allowing developers to better understand and trust AI-assisted optimization outcomes. However, the framework's performance remains dependent on training data quality and may vary across different embedded architectures and hardware configurations. Future research will focus on extending the framework for heterogeneous embedded platforms, incorporating additional hardware-aware parameters such as energy consumption and cache utilization, and developing lightweight AI models for real-time deployment. These enhancements will further improve the adaptability, efficiency, and practical applicability of AI-driven optimization solutions for next-generation embedded computing systems.

Enhanced Distributed Bandwidth Allocation Algorithm for Network Latency Reduction in IEEE 802.17 Rings

Fahd Alharbi
Electrical Engineering Department-Faculty of Engineering, Rabigh, King Abdulaziz University, Jeddah 21589, Saudi Arabia

***Abstract*—The IEEE 802.17 Resilient Packet Ring (RPR) technology is a cornerstone for the rapid expansion of metropolitan digital infrastructure. It is recognized for its robustness and spatial reuse capabilities. However, under highly dynamic and asymmetric traffic loads, standard RPR fairness algorithms often suffer from bandwidth oscillations, leading to unpredictable queuing delays and increased network latency. To address this limitation, this study introduces an Enhanced Distributed Bandwidth Allocation (EDBA) algorithm designed specifically for network latency reduction. By incorporating a filtered transit queue length into the fair rate calculation, EDBA dynamically calibrates bandwidth allocation at the source nodes before congestion propagates across the transit paths. Performance evaluations via network simulations demonstrate that the proposed algorithm significantly reduces average packet latency by up to 94%, while maintaining fairness and high throughput across the ring topology.**

***Keywords*—RPR; IEEE 802.17; bandwidth; latency; fairness**

I. Introduction

Smart cities handle the challenges of urban growth through technological integration, thereby enhancing the quality of life, upgrading security measures, and maximizing resource efficiency [1]. Smart environments are experiencing a rapid proliferation of time-critical applications. These include intelligent transportation systems (ITS), surveillance systems, real-time video streaming, grid management, financial trading, and telemedicine [2]. With the rise of real-time applications that necessitate rapid and efficient data transmission, latency is a critical performance metric in optical networks. Fundamentally, latency represents the time delay experienced between data transmission and reception. Within optical networks, this total delay comprises several components, including propagation delay through the fiber, queuing delay, and processing time at individual network nodes [3]. Metropolitan area networks (MANs) widely adopt ring aggregation architectures to ensure high availability and robust fault tolerance [4]. Resilient Packet Ring (RPR), standardized under IEEE 802.17, is a specialized ring topology designed primarily for Metropolitan Area Networks (MANs) and Wide Area Networks (WANs). The defining feature of RPR is its exceptional fault tolerance, allowing uninterrupted data transmission even during severe link failures. This robust resilience has driven its widespread adoption among MAN and WAN service providers, who traditionally rely on legacy systems like Synchronous Optical Network (SONET) or Synchronous Digital Hierarchy (SDH) architectures [5].

The Resilient Packet Ring (RPR) architecture (Fig. 1) employs dual counter-rotating optical rings to ensure robust protection and high bandwidth utilization. Each RPR node includes dedicated buffers for both local and transit traffic (Fig. 2). The primary buffer manages high-quality traffic requiring guaranteed data rates and low jitter, whereas the secondary buffer handles low-quality traffic regulated by a fairness algorithm. The primary buffer has priority to be served first, then the local buffer, as long as the secondary buffer length is less than a threshold of 1/4 of the buffer size. If the secondary buffer length exceeds the threshold, it will have a priority over the local buffer. The fairness algorithm operates via two distinct mechanisms: the aggressive method, which triggers congestion control when the secondary buffer exceeds a specific threshold, and the conservative method, which detects congestion when the combined local and transit traffic exceeds the available bandwidth for low-priority data [6].

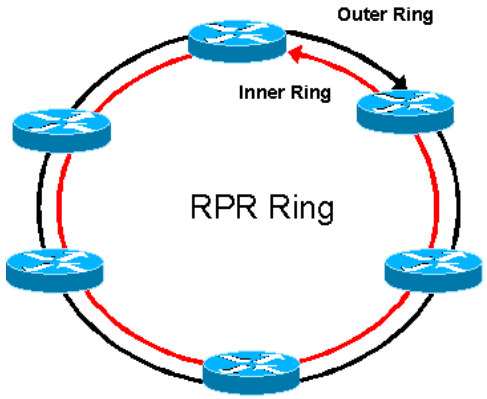

Fig. 1. The packet ring.

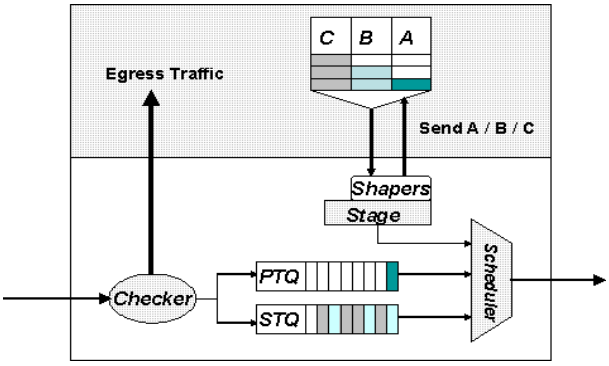

Fig. 2. RPR node architecture.

While RPR preserves the sub-50ms protection of traditional SONET/SDH rings and enhances efficiency through spatial reuse, its standard distributed fairness mechanism degrades under bursty, non-uniform traffic. Intense congestion and bandwidth competition among nodes cause fairness algorithms to oscillate severely. Consequently, this introduces heavy queuing jitter and severe packet latency bottlenecks [7].

To stabilize bandwidth allocation and mitigate these oscillations, several alternative algorithms have been proposed. For instance, the DVSR algorithm [8] monitors network nodes' demands and applies max-min fairness to eliminate oscillations, though it requires a computational complexity of *O (n log n)*, where n is the number of data flows. Conversely, the Distributed Bandwidth Allocation (DBA) algorithm [9] achieves fairness with a lower complexity of *O (1)*. Control theory has also been applied to optimize fair rate calculations. Researchers have utilized a classical PID controller to stabilize the transit buffer and regulate the bandwidth allocation process [10]. On the other hand, a fuzzy logic controller was designed to monitor the transit buffer, then increase or decrease the fair rate to maintain stability and achieve fairness [11]. Also, a combination of a Smith predictor, P-controller, and fuzzy tuning method was introduced in [6] to handle packet rings with large propagation delays. While these methods regulate bandwidth either by matching injected traffic to available capacity via DVSR and DBA algorithms or stabilizing the low-priority buffer at a target level utilizing PID and fuzzy controllers, transit traffic still accumulates in low-priority buffers during the convergence phase. This accumulation increases queuing delay and exacerbates network latency.

While the expansion of smart city frameworks requires low-latency data processing and optimal resource utilization, traditional bandwidth allocation methods introduce critical bottlenecks [12]. To address these limitations, the Distributed Bandwidth Allocation (DBA) algorithm [9] is leveraged due to its operational efficiency and low computational complexity. The objective is to design an Enhanced Distributed Bandwidth Allocation (EDBA) algorithm. By optimizing the rate-throttling process, EDBA ensures rapid latency reduction without sacrificing the foundational throughput and fairness guarantees of the IEEE 802.17 standard.

II. EDBA ALGORITHM

In this section, we review the Distributed Bandwidth Allocation (DBA) algorithm. To simplify the analysis without loss of generality, we consider a single counter-rotating path: the outer ring comprising *N* nodes, indexed sequentially along the traffic direction. Let *C* denote the available capacity allocated for low-priority traffic. The aggregate arrival rate at link *k* during the *nth* regulation interval is defined as follows:

$$A(n) = \sum_{i=1}^{M} R_i \quad (1)$$

where, R_i is the amount of data transmitted from node *i* and passing through node *k,* and *M* is the number of flows. The goal of the fairness algorithm is to maximize the fair rate F_k subject to the following conditions:

$$A \leq C \quad (2)$$

$$R_i \leq F_k \text{ , for all flows going through link } k \quad (3)$$

The algorithm uses the following equation to estimate the fair rate:

$$F_k(n) = F_k(n-1) + [C - A(n)]/M \quad (4)$$

The primary objective of the fair rate estimation equation [Eq. (4)] is to adjust *F* such that the aggregate arrival rate *A* matches the available capacity *C*. Analytical models and experimental results have established that the DBA algorithm converges to the fair rate rapidly [9]. However, as demonstrated in the subsequent section, our simulation experiments reveal that the transit buffer at the congestion point accumulates significantly during this estimation period. Because the DBA algorithm lacks a dedicated queue-draining mechanism, passing packets experience long queuing delays. Consequently, while the DBA algorithm successfully regulates bandwidth allocation, it does so at the expense of increased network latency. This structural limitation reduces the algorithm's ability to guarantee the strict Quality of Service (QoS) requirements of time-critical smart city applications; a deficiency that this work directly addresses.

The objectives of the proposed method are to regulate the fair rate and minimize the packet delay. Accordingly, the buffer length is incorporated in the fair rate calculation equation and is rewritten as follows:

$$F_k(n) = F_k(n-1) + \left[C - A(n) - \beta Q_f(n)\right]/M \quad (5)$$

where, Q_f is the filtered version of the low-priority buffer length, and the parameter β controls the speed of clearing the buffer. The filtered buffer length is updated as follows:

$$Q_f(n) = (1-\alpha)Q_f(n-1) + \alpha\, Q_i(n) \quad (6)$$

where, Q_i is the instantaneous value of the low-priority buffer length, and the filter coefficient is $\alpha \in [0,1]$ [13].

III. RESULTS AND DISCUSSION

In this section, we conduct two simulation experiments. The first experiment is the simple congestion points scenario shown in Fig. 3, where all links have the same capacity of 622 Mbps, and each link has a propagation delay of 0.1 ms. All data flows are greedy and start at time 0. The measurement time interval is set to T=1ms. The experiment is conducted using the RPR simulator [14].

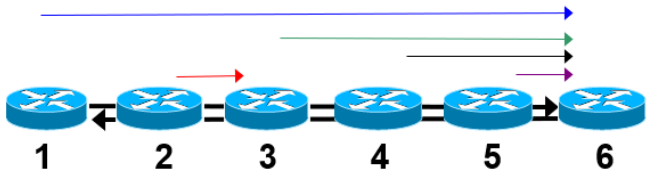

Fig. 3. Simple congestion points scenario.

In this scenario, there are two congestion points. The first congestion point is between switches 5 and 6, where four flows compete for the bandwidth, and a fair share is 155 Mbps. The second point is between switches 2 and 3, where the competing flows are flow (1,6) and flow (2,3). Since flow (1,6) would be limited to the fair share reported by switch 5, flow (2,3) should be able to utilize the remaining bandwidth on link 2-3 and transmit at a rate of 467Mbps. The performance of the

proposed EDBA algorithm is evaluated against two different algorithms. The DBA algorithm is considered as a rate-based algorithm, while the PID controller is considered a queue-based algorithm. The evaluation focuses on the ability to achieve fairness and high resource utilization and also reduce the network latency. The performance of the DBA algorithm, the PID controller, and the proposed EDBA in regulating the bandwidth allocation are shown in Fig. 4, Fig. 5, and Fig. 6, respectively. All algorithms successfully converge very quickly, enabling all flows to achieve their fair shares.

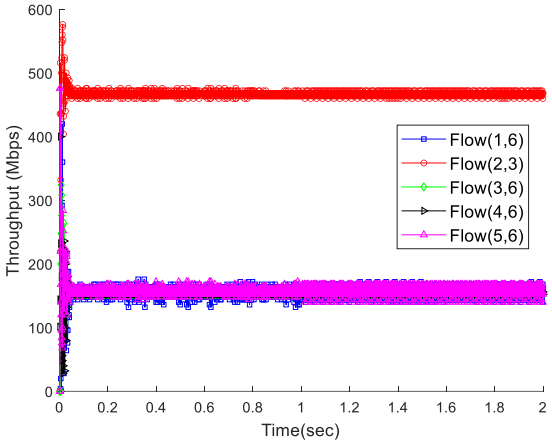

Fig. 4. Simple congestion points scenario: flows convergence (DBA).

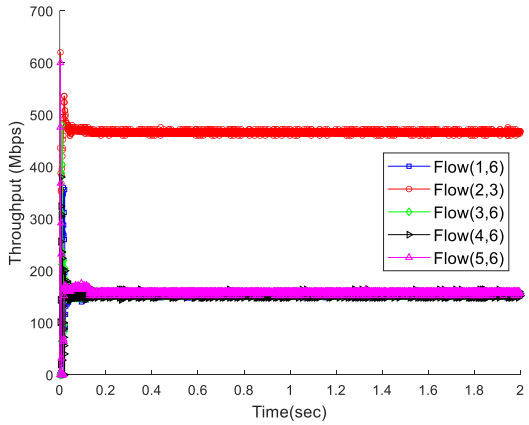

Fig. 5. Simple congestion points scenario: flows convergence (PID).

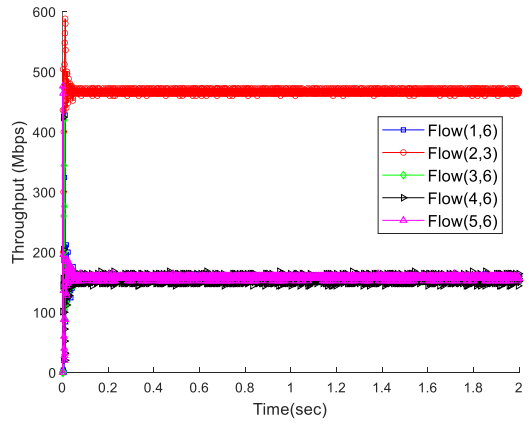

Fig. 6. Simple congestion points scenario: flows convergence (EDBA).

Due to the simultaneous congestion at switches 2 and 5, the low-priority transit buffer occupancy at these nodes accumulates significantly, reaching approximately 25% of the total buffer capacity during the convergence period, as illustrated in Fig. 7. These results demonstrate that the DBA algorithm cannot clear these queues once accumulation occurs.

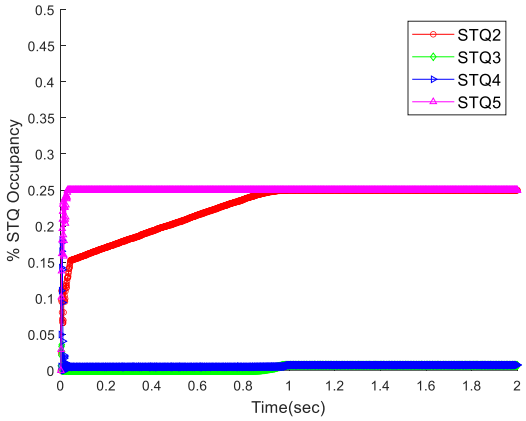

Fig. 7. Simple congestion points scenario: buffer length (DBA).

On the other hand, maintaining a stable queue at a pre-defined target level is a primary objective of the PID controller. Consequently, as illustrated in Fig. 8, the low-priority buffer occupancy at the bottleneck points stabilizes at the target threshold of one-sixteenth (6.25%) of the total buffer capacity. In contrast, the proposed EDBA algorithm successfully empties the accumulated traffic from the low-priority transit buffers, as demonstrated in Fig. 9. By dynamically integrating the filtered buffer occupancy metric Q_f, into the modified fair rate estimation [Eq. (5)], EDBA is capable of clearing the ring transit queues while fully preserving the throughput and fairness mandates of the IEEE 802.17 standard.

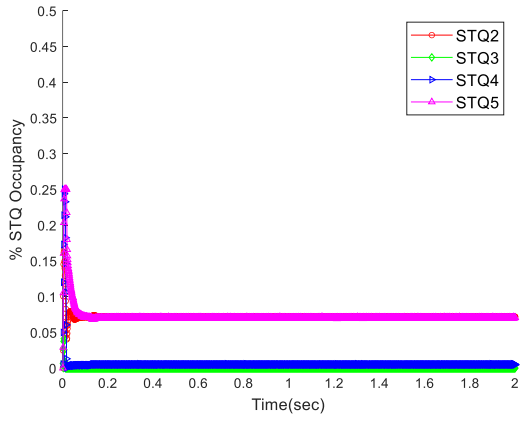

Fig. 8. Simple congestion points scenario: buffer length (PID).

For all algorithms, we compare the delay of packets transmitted from switch 1 to switch 6, where they pass through two congestion points. Fig. 10 illustrates the transient and packet network latency curves for the three evaluated algorithms. As expected from the buffer occupancy behaviors, the DBA algorithm exhibits a severe, continuous growth in network delay during the transient convergence period, ultimately saturating at a high steady-state latency of

approximately 18.124 ms. This rapid, continuous increase confirms the accumulation of low-priority traffic within the transit buffers; without a dedicated queue-clearing mechanism, packets are subjected to persistent, cumulative queuing delays.

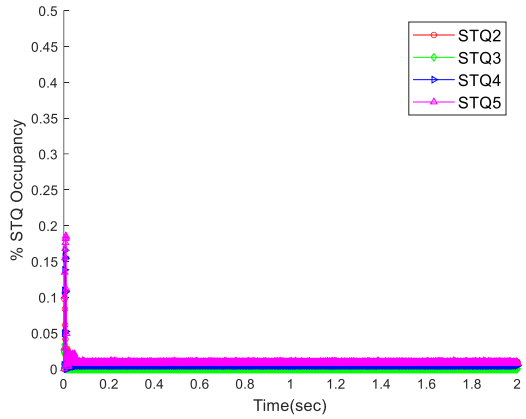

Fig. 9. Simple congestion points scenario: buffer length (EDBA).

In contrast, the queue-based PID controller successfully stabilizes the latency curve, reducing the network delay to roughly 5.383 ms. Because the PID algorithm regulates the transit buffer to a specific target length, it prevents the unbounded delay increase observed in the DBA algorithm. However, it still maintains a permanent, non-zero queuing overhead to enforce its operating setpoint.

Remarkably, the proposed EDBA algorithm outperforms both the DBA algorithm and the PID controller. The EDBA network latency curve drops quickly and stabilizes at approximately 1.104 ms. By emptying the low-priority transit queues using the filtered buffer length variable, Q_f , EDBA almost eliminates queuing delays. This represents an approximate 94% latency reduction compared to DBA and a 79% reduction compared to the PID controller, demonstrating EDBA's capability to sustain the strict low-latency requirements demanded by time-critical smart city applications.

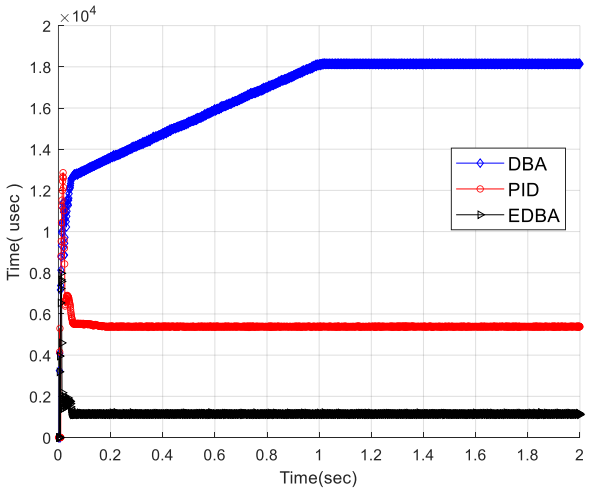

Fig. 10. The transient and packet network latency curves.

In the second experiment (Fig. 11), all flows are greedy and start at time 0. In this scenario, data packets transmitted from Switch 1 to Switch 6 pass through multiple congestion points. The fair-share bandwidth at each congestion point is 311 Mbps because each point is shared by only two flows.

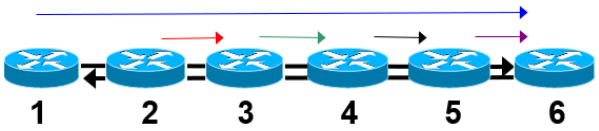

Fig. 11. Multiple congestion points scenario.

Similarly, the DBA algorithm, PID controller, and proposed EDBA algorithm successfully regulate the bandwidth allocation. As depicted in Fig. 12–14, each flow consistently achieves a bandwidth of 311 Mbps.

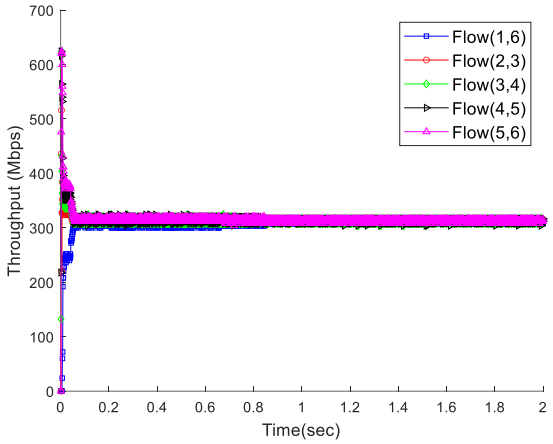

Fig. 12. Multiple congestion points scenario: flows convergence (DBA).

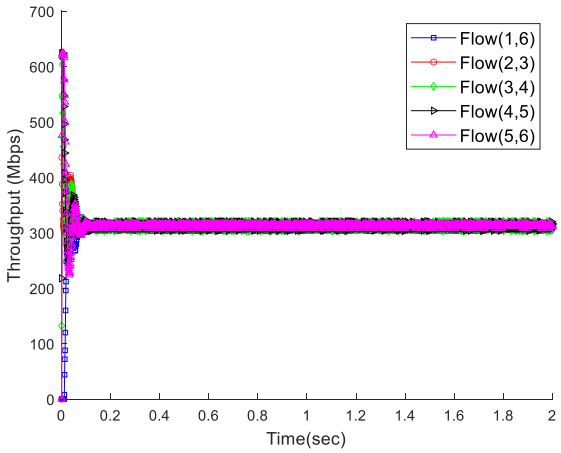

Fig. 13. Multiple congestion points scenario: flows convergence (PID).

This scenario introduces four simultaneous congestion points at switches 2 through 5. As illustrated in Fig. 15, the low-priority transit buffer occupancy at these nodes builds up rapidly, reaching roughly 25% of buffer capacity during convergence. This highlights a key limitation: the DBA algorithm lacks the capability to drain these queues once accumulation takes place.

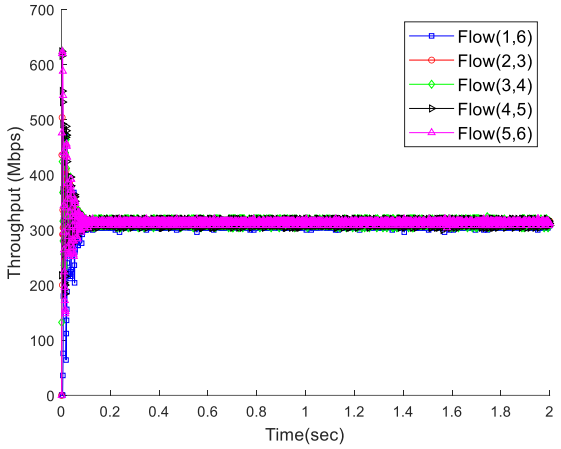

Fig. 14. Multiple congestion points scenario: flows convergence (EDBA).

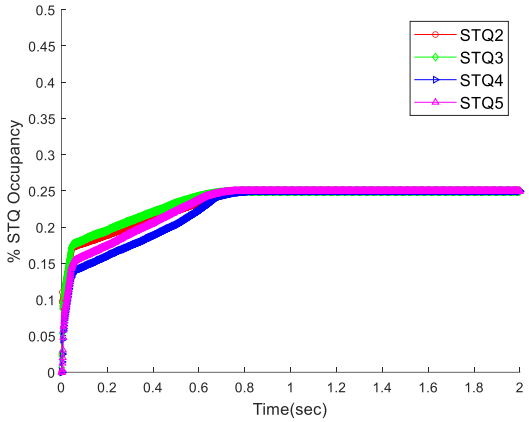

Fig. 15. Multiple congestion points scenario: buffer length (DBA).

While the PID controller focuses primarily on stabilizing the queue at a predefined target level, thereby holding the low-priority buffer occupancy at the bottleneck points to 6.25% of the buffer capacity (Fig. 16), the proposed EDBA algorithm successfully evacuates the accumulated traffic (Fig. 17). This is achieved by dynamically integrating the filtered buffer occupancy measurement Q_f , into the fair rate estimation equation [Eq. (5)]. Consequently, EDBA clears the ring transit queues without compromising the throughput and fairness mandates of the IEEE 802.17 standard.

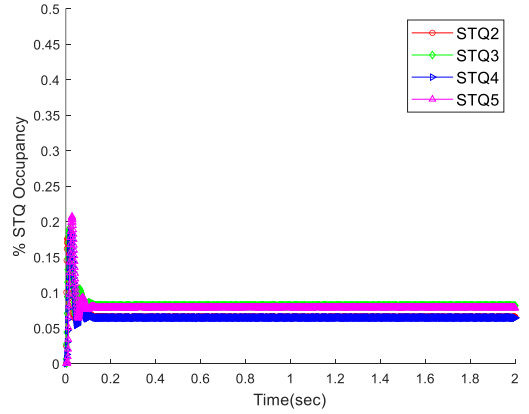

Fig. 16. Multiple congestion points scenario: buffer length (PID).

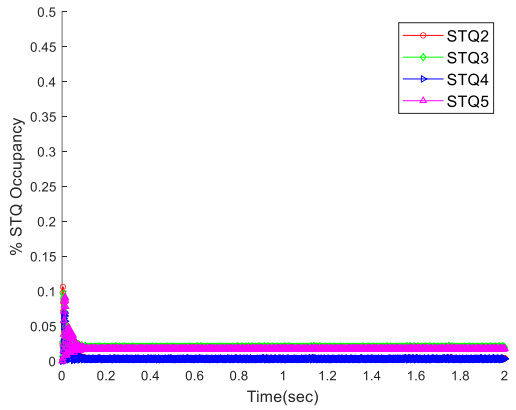

Fig. 17. Multiple congestion points scenario: buffer length (EDBA)

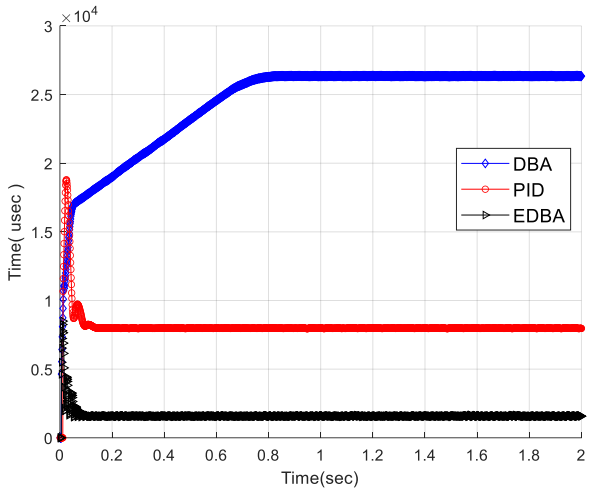

Fig. 18. Flow (1,6) packet delay.

Fig. 18 illustrates the network latency performance for the three evaluated algorithms under the multi-congestion scenario, specifically showing the delay of Flow (1,6) packets transmitted from switch 1 to switch 6. Because these data packets pass through multiple concurrent traffic bottlenecks, the DBA algorithm exhibits a continuous increase in latency during the transient phase, reaching a delay of approximately 26.34 ms. Furthermore, since the rate-based DBA algorithm lacks a queue-draining mechanism, the packet accumulation that builds up in the transit buffers during the fair-rate estimation period exposes all passing packets to high latency.

The queue-based PID controller successfully mitigates network latency growth. At the beginning of congestion, the PID controller experiences a sharp, transient overshoot; however, it rapidly reduces the latency within a few milliseconds, settling at a delay of approximately 7.965 ms. While effective at reducing network delay, the PID controller must maintain its transit queues at a non-zero setpoint to operate, thereby leaving a permanent queuing overhead in the network path

The proposed EDBA algorithm outperforms both approaches. Upon the initialization of concurrent flows, EDBA effectively limits the transient delay spike. Driven by the filtered buffer occupancy metric, Q_f , the rate-throttling

mechanism immediately drains the transient queue accumulation. Consequently, the latency curve decays sharply and stabilizes rapidly, maintaining a remarkably low delay of approximately 1.571 ms.

This optimized behavior translates to substantial performance improvements for delay-sensitive network infrastructures: a 94.0% latency reduction compared to the rate-based DBA algorithm and an 80.0% latency reduction compared to the queue-stabilizing PID controller. By completely evacuating the transient queues rather than containing them, the EDBA algorithm proves highly effective at sustaining the strict, low-latency Quality of Service (QoS) required by next-generation smart city applications.

IV. CONCLUSION

This study presented the Enhanced Dynamic Bandwidth Allocation (EDBA) algorithm, a novel queue-aware framework designed to mitigate transient congestion and optimize latency performance in IEEE 802.17 Resilient Packet Ring (RPR) networks. Experimental evaluations under concurrent multi-congestion scenarios demonstrated that while the conventional rate-based DBA algorithm fails to drain accumulated buffers and the PID controller incurs a permanent queuing overhead, the proposed EDBA algorithm completely evacuates transient queues. Specifically, EDBA maintains a stable, low steady-state delay of approximately 1.571 ms, yielding a 94.0% latency reduction relative to the DBA algorithm and an 80.0% reduction compared to the PID controller. By successfully balancing transient queue evacuation with the strict throughput and fairness mandates of the IEEE 802.17 standard, EDBA proves to be a highly effective solution for sustaining the low-latency Quality of Service (QoS) required by next-generation smart city applications.

While the proposed EDBA algorithm achieves exceptional performance using a static filtering configuration, adaptive parameter tuning remains an avenue for future exploration. Subsequent research will focus on developing an adaptive tuning mechanism for the buffer clearing parameter, β, and the buffer filter coefficient, α. Dynamically adjusting these parameters based on real-time network dynamics will allow the algorithm to maintain optimal responsiveness across varying traffic intensities.

***Abstract*—Cloud computing (CC) has grown as a core component of modern computing facilities, providing users with adaptable, on-demand services. In dynamic environments, the effective utilization of resources is significant for performance, cost-effectiveness, and user satisfaction. The optimization of resource allocation is important in CC due to the dynamic and complex nature of cloud infrastructure. This study suggests a hybrid resource allocation procedure that combines Double Q-learning(DQ), a reinforcement learning (RL) approach, with meta-heuristic algorithms, including the Whale Optimization Algorithm (WOA), and it is compared with Particle Swarm Optimization (PSO), Ant Colony Optimization (ACO), and Genetic Algorithms (GA) to optimize task allocation in CC settings. This combined system overcomes task allocation challenges such as usage of resources, energy consumption, and SLA compliance by integrating Q-learning's adaptive decision-making skills with meta-heuristic methods' global search efficiency. The proposed approach dynamically adapts optimum resource allocation guidelines while considering a variety of options for near-optimal task scheduling and resource assignment. The results of the experiment reveal that the hybrid strategy outperforms the PSO, ACO, and GA techniques in terms of makespan, reaction time, throughput, resource utilization of resources, cost, and rate of resource violation. This study provides an effective approach to handling complex resource allocation difficulties in a variety of dynamic cloud environments.**

I. Introduction

The rise of CC and services indicated the beginning of a new era of computing, giving numerous advantages, including expansion, flexibility, and affordability. Resource Allocation in CC is the process of distributing resources across different users and applications in the cloud. These resources include memory, computational power, storage, and network bandwidth [1]. The exponential rise of CC users has resulted in an extraordinary surge in demand for computing resources to perform cloud services. As a result, it is necessary to evaluate currently available resources such as virtual machines (VMs), CPU, RAM, and storage before allocating cloud services. The objective of resource allocation in the cloud is normally to assign resources to tasks (or virtual machines) in such a way that specific objectives are optimized, such as minimizing makespan, energy consumption, and maximizing resource utilization, throughput, and so on.

A. Cloud Computing

CC is a technological paradigm that enables customers to pay as they go for computing resources (e.g., servers, storage, databases, networking, software, and analytics) via the internet ("the cloud"). The design eliminates the need to own and manage physical data centers or servers, resulting in increased adaptability, scaling, and cost-efficiency. It is a model that provides on-demand access to a common pool of configurable computing assets (such as networks, storage, servers, applications, and services). These resources can be deployed and released with little management effort or intervention from the service provider. Cloud service models include Infrastructure as a Service (IaaS), Platform as a Service (PaaS), and Software as a Service (SaaS). IaaS offers virtualized computational assets such as virtual computers, storage, and networks. PaaS allows developers to construct, test, and launch apps without having to manage the structure that underlies them. Software as a service (SaaS) is delivered via the internet, generally through a web browser.

Resource allocation is a fundamental part of CC. It includes controlling and allocating the underlying virtual and physical resources in order to ensure efficient operation, fulfill user requests, and maintain service-level agreements. In CC, resource allocation focuses on optimizing resource distribution to improve efficiency and reduce costs while maintaining stability and scalability. It entails determining which resources to dedicate to specific activities, how much to give away, and for how long [2]. The basic concepts of resource allocation include the following.

Elasticity: The ability to gain resources in a flexible manner is seen as the fundamental reason for implementing a CC system. Elasticity primarily supports the ability to build and

shrink virtual resources dynamically in response to the needs of cloud users. Elastic resource allocation is critical for properly managing cloud resources based on customer demand and cloud service provider (CSP's) resources [3]. Elastic resources are programs and infrastructure that can be accessed on request when traffic or workloads increase. Cloud companies like AWS and Google Cloud use elastic resources as an enterprise model to bill consumers on demand, much like a utility bill. The cloud ecosystem is built on these supply and demand economic cycles. EC2 servers are an outstanding example of elastic resources. If a firm only needs two servers to host their website but experiences a holiday traffic increase, they may simply deploy more elastic resources by increasing the number of EC2 servers from two to four. Once the traffic decreases, they can reduce the server count to two.

Multi-tenancy: Multi-tenancy refers to having several tenants. This refers to a collection of users, resources, or services. The multi-tenant application was designed so that multiple users could access the same logic at the same time. A Software-as-a-Service (SaaS) provider can run numerous instances of the application and deliver web access to multiple customers, each with their own particular configuration. Such a model enables data isolation because each tenant's data is invisible to others.

QoS (Quality of Service): In CC, QoS is a metric used to assess the efficiency of a service, such as a network or cloud service. It is a method of evaluating the functionality of a service and ensuring that it fulfills the requirements. QoS measurements may include availability, reliability, and response time. The Cloud environment is a massive collection of virtually accessible resources that carry out millions of computing operations in real time for resource provisioning. Allocation and scheduling are two key components of providing for quality of service. This covers sophisticated modules including identifying work requirements, determining resource availability, making allocation decisions, and scheduling activities. In the current setting, it is challenging to manage cloud resources because service providers aim to deliver resources to consumers at productive cost and time[4].

Cost Efficiency: Inefficiencies in the cloud tend to manifest through over-provisioning and inefficient use of resources, which has the effect of increasing costs of operation. Common problems range from using too much CPU, storing too much data, and wasting on networking. If businesses overprovision their clouds, they pay for services not being utilized fully. Proper cloud cost optimization solutions are imperative in a bid to avoid such problems and enhance efficiency.

Workload Management: Strategic resource allocation, load balancing, and automation are required for effective cloud workload management to provide the highest achievable performance, efficiency, and cost savings in multiple cloud services and environments. Effective workload distribution in data centers enables business organizations to increase IT productivity, cut costs, and improve system effectiveness.

Dynamic resource allocation refers to the real-time assignment and reassignment of computing resources (e.g., CPU, memory, storage, and bandwidth) according to changing demands from users, software, or services in a cloud infrastructure. This method guarantees optimal resource utilization, cost efficiency, and responsiveness to dynamic workloads. Resource provisioning was done employing VM technology. It is argued that using a virtualized environment will reduce average job response times in addition to performing tasks on the basis of available resources. Consequently, users are allocated virtual machines based on work criteria. Efficient and dynamic utilization of cloud resources could help distribute the load and prevent occurrences such as system performance degradation. Meta-heuristics are techniques used to solve issues with a broad domain space that are difficult to research using conventional methods.

They are widely used in CC for resource allocation because of their capacity to handle complicated, multi-objective, and dynamic optimization problems. These algorithms have grown dynamically in previous decades. Scholars have been encouraged to use meta-heuristic algorithms to solve NP-hard issues. The benefit of employing these types of algorithms is that they can detect the best solution with less processing effort and fewer iterations than simple heuristic methods. The meta-heuristic method has some benefits, including simplicity, flexibility, source-independent solutions, and the ability not to become trapped in local optimum situations [5]. For effective resource allocation on the cloud, certain meta-heuristic algorithms such as ACO [6], PSO [7], Artificial Bee Colony (ABC)[8], Rock Hyrax Optimization (RHO)[9], and Bacterial Foraging Optimization (BFO)[10] were used. Resource distribution optimization methods are used to efficiently make allocations while satisfying constraints such as cost, power, and performance, and establishing balance among conflicting goals is very important in CC. The research goals are as follows:

- To design and test a hybrid resource allocation model incorporating Double Q-learning (DQ) and meta-heuristic algorithms to schedule tasks and allocate resources in dynamic CC environments efficiently.
- To compare the designed hybrid approach with other meta-heuristic algorithms such as Particle Swarm Optimization (PSO), Ant Colony Optimization (ACO), and Genetic Algorithm (GA) in cloud computing environments.
- To attain optimal cloud performance metrics like makespan, response time, throughput, resource utilization, cost, and rate of resource violation.

The remaining part of this research is structured as follows. Section II discusses some existing works on resource allocation in cloud computing through reinforcement learning and meta-heuristics. Section III presents the proposed hybrid methodology by integrating Double Q-learning and the Whale Optimization Algorithm. Section IV discusses experimental findings and observations, and Section V concludes the work with key findings and future work directions.

II. Literature Review

In recent years, with the growing complexity of cloud resource scheduling requirements and the dynamic nature of cloud workloads, machine learning, deep learning,

reinforcement learning, and meta-heuristic optimization have played an increasing role in recent studies on cloud resource allocation. Their focus is on better use of resources, optimization of task scheduling, workload forecasting, load balancing, cost optimization, and service quality. Recently, there has been a lot of development going on in intelligent cloud resource management, which is summarized in the following studies.

Zheng et al. (2024) designed a prediction model by using XGBoost and LSTM to predict workload trends over time. The model is trained on historical data from an enormous cloud system with 1000 servers and more than 52 million data points. A dynamic resource scaling strategy is proposed with the use of the output of the prediction model and real-time system status inputs to make active allocation decisions [11]. Alizadeh et al. (2024) suggest an autonomous VM resource allocator based on the Clipped Double Deep Q-Learning (CDDQL) Algorithm and the meta-heuristic PSO. The tasks are prioritized through the use of the PSO algorithm, while CDDQL serves as the core of the autonomous system (Auto-CDDQL) in order to assign the proper VM resources to the tasks[12].

Zhang et al. (2024) present an action-constrained deep RL (DRL) technique for safely allocating computer resources and providing an optimal resource scheduling strategy. Task scheduling in dynamic cloud-based systems is a challenging task due to varying workload requirements, changing resource availability, and inconsistent task priorities. Traditional methods of optimization are generally inefficient in handling complex limitations [13]. To solve the above problems, Bajpai et al. 2024 introduce the Q-Whale algorithm (QWA) and the SARSA-Whale algorithm (SWA), a novel hybrid method that combines the WOA and RL methods [14]. Khani et al. review recent works on resource distribution in 5G cloud-based radio access networks (C-RAN) using DRL algorithms. It explores the potential of DRL to learn complex making decisions policies without intervention [15].

Gogula et al., 2024 try to formulate a task handling framework with decision-making capability to choose the best resource in real time for managing different and complicated applications on Virtual machines [16]. It applies a modified PSO in order to fulfill the user's deadline. Gongada et al., 2024 suggest a new task scheduling optimization framework that integrates Fruit Fly Optimization (FFO) and Convolutional Neural Networks (CNN). It highlights the importance of efficient resource allocation and management in CC to meet increasing demands for computing resources at reduced costs and enhanced overall system performance [17].

Aditi et al., 2025 compare a number of DL models, i.e., Recurrent Neural Networks, Residual Networks (ResNets), and CNN, to optimize the utilization of cloud resources and system performance [18]. Muniswamy et al.,2024 present a joint optimization of LB and resource allocation in the cloud with the help of an optimal container management method. It aims to enhance scheduling efficiency and be cost-saving through upgrading the requested remotely by users' container schedule. An enhanced backtracking search optimization (IBSO) method is applied to allocate resources between end-users/IoT devices and the cloud subject to service-level agreements [19]. Table I lists the recent related studies discovered in the literature for resource allocation in CC.

TABLE I. RELATED STUDIES IN THE LITERATURE FOR RESOURCE ALLOCATION IN CC

Author /Year	Methods	Data set	Evaluation Criteria	Limitations
Zheng et al., 2024	XGBoost and LSTM	Historical and real time data	Resource Utilization, Resource Violation Rate, Energy Efficiency	It works well on weel crafted features, not applicable for real time , computationally expensive
Alizadeh et al., 2024	CDDQL	c-hilo	Makes span, response time, task completion, resource utilization, and energy consumption rate	Computational complexity, takes a long time to converge, overfits to specific patterns
Zhang et al., 2024	DRL	Simulated data	Cost, delay, and security	High computational cost, long training time, scalability issues
Gogula et al., 2024	PSO	User-generated data	Resource utilization	Premature convergence, depends heavily on inertia weight and learning factors
Gongada et al., 2024	FFO and CNN	Historical data	Resource utilization and average response time	Only suitable for image processing
Aditi et al., 2025	CNN	MNIST dataset	Accuracy	Only suitable for image processing
Muniswamy et al.,2024	IBSO	Simulated data	Energy consumption, number of active servers, number of interruptions, total cost, runtime, and statistical measures.	Not suitable for real-time; requires tuning

Existing studies on cloud resource allocation have several limitations. Most of the approaches, such as XGBoost, LSTM, and DRL, are computationally costly, take a long time to train, and are not suitable for real-time applications. Approaches such as PSO are prone to premature convergence and are highly sensitive to parameter settings, whereas CNN-based models are primarily restricted to image processing tasks and are not suitable for application in different cloud environments. Besides, certain approaches have a tendency to overfit to particular data patterns and are not as agile as needed to handle dynamic and unpredictable workloads of cloud computing.

In spite of significant progress, there is an evident research gap in creating adaptive, scalable, and efficient resource allocation techniques for adaptive cloud environments. Existing works do not properly compromise between decision accuracy and global search ability, causing inefficient task scheduling and resource handling. Relatively few pieces of work have dealt with combining reinforcement learning methods such as Double Q-learning with meta-heuristic optimization techniques to combine local decision-making and global optimality. In addition, scarce research critically analyzes such hybrid approaches against multiple performance

measures like makespan, cost, response time, and SLA fulfillment.

III. METHODOLOGY

This section describes the technique utilized to achieve the research objectives. The hybrid technique utilizes the adaptive decision-making capabilities of Q-learning and the global exploration efficiency of meta-heuristic algorithms. The framework shown in Fig. 1 combines the information of the cloud workload with adaptive decision-making (based on Double Q-Learning) and global exploration and local exploitation (WOA). For comparison, PSO, ACO and GA are some alternative optimization techniques. The framework takes care of resource needs, checks out the candidate allocations, and generates optimal resource allocations taking into account utilization, performance, QoS, and SLA restrictions.

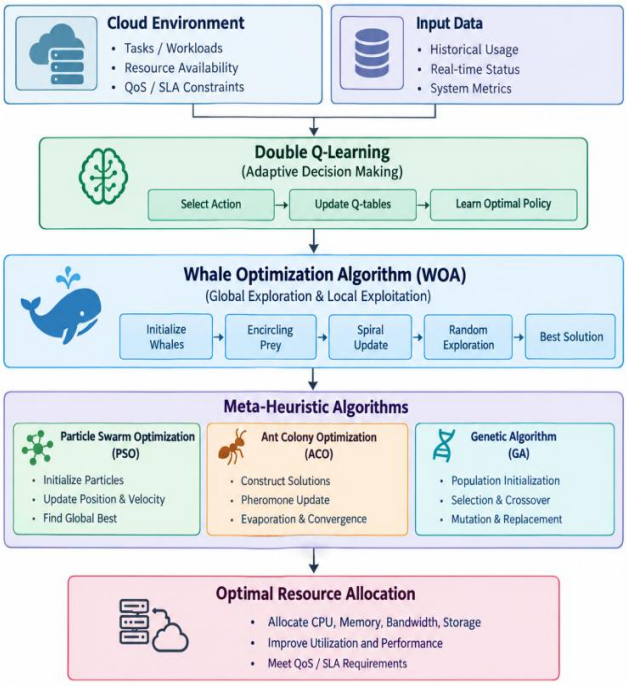

Fig. 1. Proposed hybrid double Q-learning and whale optimization algorithm framework.

A. Double Q-Learning

Q-learning is a RL method that teaches an agent how to perform optimal behaviors in a given environment in order to maximize cumulative rewards. It belongs to the value-based technique family and is especially beneficial for decision-making situations in which the agent communicates with the surrounding environment over time. The Bellman equation is used by the Q-learning algorithm to repeatedly update the Q-value for each state-action pair.

$$Q(s,a) \leftarrow q(s,a) + \alpha\{r + \max(Q(s',a') - Q(s,a)]) \quad (1)$$

where, Q(s,a): current estimate of the Q –value ,α , the learning rate , r –immediate reward after the action α in state s, γ-discount factor[20].

An improved version of the initial Q-learning algorithm, double Q-learning was derived to solve the problem of overestimation of the action value. In standard Q-learning, the value of an action is estimated using the maximum Q-value in the Q-table (or Q-function) for the subsequent state. As the action of maximum value is selected based on a noisy estimate instead of the actual value of the action, this could be a cause of overestimation. This bias of overestimation can cause inefficient policies or reduce learning speed. To overcome this bias, double Q-learning uses two separate Q-value estimators (Q1 and Q2). The steps in Double Q-learning are as follows.

Step 1: Two Q-value tables: Instead of maintaining a single Q-value table, Double Q-learning maintains two separate Q-value tables: $Q_1(s,a)$ and $Q_2(s,a)$ The two are updated independently.

Step 2: Action Selection: During learning, one of the Q-tables is used to select an action while learning.

Step 3: Update Process: While updating the Q-values, Double Q-learning employs the other Q-table to avoid the overestimation bias:

The action selected from the first Q-table (Q_1)is assessed according to the second Q-table (Q_2).

Particularly, the update of Q_1 and Q_2 is computed as follows:

$$Q_1(s,a) \leftarrow Q_1(s,a) + \alpha(r + \gamma Q_2(s', \arg\max_{a'} Q_1(s',a')) - Q_1(s,a)) \quad (2)$$

$$Q_2(s,a) \leftarrow Q_2(s,a) + \alpha(r + \gamma Q_1(s', \arg\max_{a'} Q_2(s',a')) - Q_2(s,a)) \quad (3)$$

This update employs the Q-table, which was not utilized to make the action choice, to calculate the next state's value and minimize overestimation of actions' values.

B. Whale Optimization Algorithm (WOA)

The WOA is a population-based optimization algorithm inspired by nature and based on humpback whale hunting behavior. The algorithm used belongs to the family of algorithms for swarm intelligence and was motivated by humpback whales' social behavior and hunting skills, especially their bubble-net feeding strategy. The WOA algorithmic Steps are:

- Randomly initialize a set of whales (solutions). Each whale carries an occupation in the solution space.
- Update Position: The algorithm updates the position of a whale by using three different strategies.
- Encircling Prey: Update the position of the whale using the distance between the current position of the whale and the best solution encountered so far (the prey).
- Spiral Update Position is inspired by the spiraling movement of whales while heading to the target. The update uses a spiral function in the equation.
- Random Exploration: During exploration, the algorithm uses random search to scan across the solution space.

- The above improvements make the algorithm mix global exploration (scanning widely across the solution space) with local exploitation (scanning narrowly around the current best so far).
- Objective Function Assessment: Each whale assesses the objective function (fitness function) so that it can identify how good the solution is. The fitness function is problem-specific.
- Update Best Solution: The algorithm holds the best solution obtained during the search and updates it.
- Termination: The algorithm updates the position of the whales at regular intervals and examines solutions until a stopping condition is met.

The flowchart for the hybrid Q-Whale approach is shown in Fig. 2.

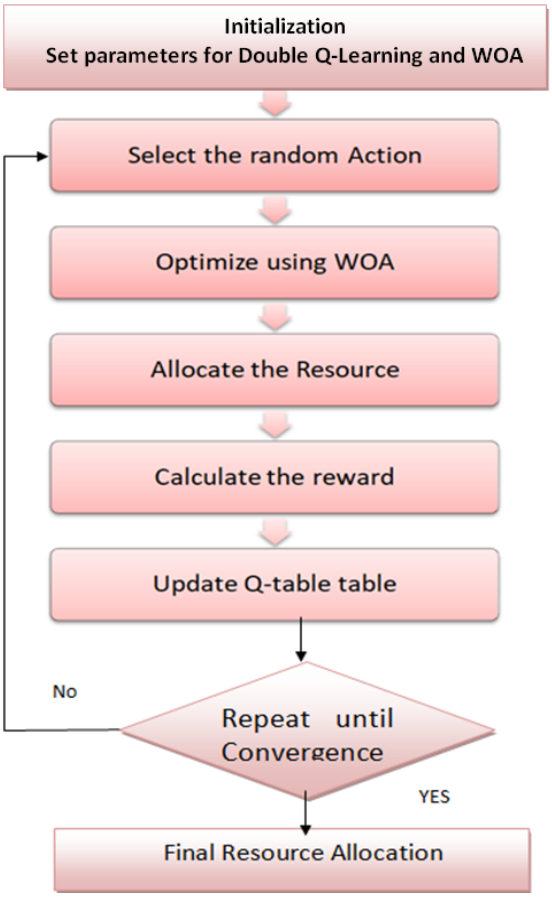

Fig. 2. Flowchart for the hybrid double Q-learning and WOA.

C. Particle Swarm Intelligence (PSO)

PSO is a school of fish or flocking-inspired algorithm that has been highly successful in addressing complicated optimization challenges, particularly in cloud computing resource allocation, communication networks, and energy consumption. In resource allocation, PSO can be utilized to allocate the resources (e.g., CPU capacity, memory, bandwidth, or storage) among the various tasks, users, or services in a way that is most cost-effective, efficient, and satisfies Quality of Service (QoS) needs.

PSO consists of a collection of candidate solutions known as particles, and each particle is associated with one of the alternatives in the solution space. All the particles move their position in the solution space based on their local information and information of adjacent particles. The key steps in PSO are:

- Problem Description: Particle position indicates the possibility of resource allocation. For instance, an allocation can be manifested as a vector of resource allocation over many tasks or users. The objective function relates to how usable or optimal a given allocation is, e.g., least cost, energy consumption, or makespan not surpassing intermediate resource limits.
- The initialization step: Particles are initialized randomly in a solution space. Each particle is an instance of a unique distribution of resources.
- The fitness function calculates the performance metrics (e.g., cost, QoS, energy usage) and requirements (e.g., SLA, resource availability) of a solution of each particle. For example, in CC, the fitness function can optimize idle resources, load balance, or reduce energy consumption with respect to quality of service constraints.
- Location and Velocity Update: The position and velocity of each particle are updated based on the PSO equations, considering its individual best and global best solution. The algorithm encourages good search in the solution space by a balance of exploration (search for new areas) and exploitation (local improvement of the current good solutions).
- Convergence: Particle positions are updated at intervals and converge to the global optimal solution, and make the fullest use of the resources in the long run. The algorithm stops when repetitions are at maximum or when improvement in solution stops [21].

D. Ant Colony Optimization (ACO)

Ant Colony Optimization (ACO) is a nature-based optimization algorithm imitating ants' foraging behavior and, more significantly, how pheromone communication enables them to select the best path to food sources. ACO performs best on extremely large combinatorial optimization problems such as CC resource allocation, network optimization, scheduling jobs, and energy distribution. The general ACO method for resource allocation is as follows:

Initialization: The pheromone values are initialized on each edge (or decision variable) of the graph at the beginning. Ants are allocated to the graph in an effort to avoid experimenting with various schemes of resource allocation.

Solution Construction: One ant develops the solution by moving from a node (resource) to another, applying a probability decision rule on pheromone values and a heuristic function.

Pheromone Update: Once the solution is constructed, ants consider the quality of the solution with respect to an objective function (e.g., cost or performance). The concentration of pheromone on traveled paths is updated based on solution quality. Paths to better quality solutions have greater pheromone concentration and thus are more likely to be visited by following ants.

Evaporation: So that locally optimal solutions are avoided, the pheromone concentration decreases over time, and thus the impact of past routes is restricted.

Convergence: With more and more ants searching through different allocation paths, at some point the process converges to a phase where it uses an approximately optimal or optimal means of resource allocation.

ACO provides an efficient and universal solution to resource optimization in CC computer networks. Its capability of exploring diversified solutions and wide application in various situations renders it qualified for adaptive large-scale cloud systems with a dynamic nature. However, scalability, dynamic adaptability, and multi-objective optimization for practical use are all areas to be tackled [22].

E. Genetic Algorithms (GA)

Genetic Algorithms (GAs) are a powerful, nature-inspired optimization method based on genetics and natural selection. GAs have been used successfully to solve allocation problems in numerous fields, including cloud computing. Genetic algorithms are best suited to address complicated optimization problems, such as the resource allocation problem in cloud infrastructure, where the solution space is extremely huge, and objectives may be conflicting.

GAs operate on a population of possible solutions in which each solution is an individual member of the population. In cloud resource allocation, there can be various representations based on the given problem, which are: Chromosome Encoding: A GA individual or a chromosome might represent resource allocation task-specific. Each gene of the chromosome would be coded to some activity or resource, and resource allocations would be calculated based on the value of the gene (e.g., virtual machine to an activity, CPU or memory allocated, etc.). The standard Genetic Algorithm resource allocation process is the following:

Initialization: Random population of solutions (chromosomes) is created. Each solution contains one valid resource allocation.

Fitness Test: Each individual (resource allocation) is evaluated on the basis of a fitness function. The quality of the solution is defined by the fitness function. For example, it may penalize allocations that use more than available resources, excessive power consumption, or long runtimes.

Selection: Fittest individuals are selected on the basis of fitness degree. One may apply different selection strategies, for example:

- Roulette Wheel Selection: Probabilistically select individuals based on fitness.
- Tournament Selection: A method of choosing a pair at random from a set of people and selecting the winner.

Crossover (recombination) is an operation wherein two parent solutions are blended to produce offspring. In the case of resource allocation, this would be swapping portions of the chromosome (resource allocations) between the two individuals with the hope of creating new resource allocation solutions.

Mutation creates small random changes in offspring. It is done by assigning an asset at random to some other task or by assigning assets to replicate varying dynamics in the environment.

Replacement: The offspring are then inserted into the population, replacing the originals partially, usually based on their fitness.

Termination: The above process is run for a finite number of generations or until it achieves an optimal solution (i.e., population converges). Genetic algorithms are best suited to address resource allocation problems in cloud computing. They can search large spaces and optimize multi-objective problems with high levels, making them best suited to optimize resources in clouds. Scalability, variable environments, and convergence must be addressed prior to being implemented in actual clouds[23].

Algorithm: Hybrid Q-Whale Resource Allocation

Input: Cloud tasks, available resources, QoS/SLA constraints
Output: Optimized resource allocation
1. Initialize Q1, Q2 and the whale population.
2. Evaluate the initial whale solutions.
3. Identify the best whale solution.
4. Repeat until convergence:
   a. Observe the current cloud state.
   b. Select an action using Double Q-Learning.
   c. Execute the action and obtain the reward.
   d. Update Q1 or Q2 using the other Q-table.
   e. Update whale positions using WOA.
   f. Evaluate candidate allocations.
   g. Update the best solution.
   h. Check resource and QoS/SLA constraints.
5. Return the best resource allocation.

IV. RESULTS AND FINDINGS

This section discusses the tools and the parameters used to evaluate the resource allocation strategies. The proposed DQ-Whale resource allocation framework has been simulated and tested in the CloudSim simulation environment. A diverse cloud infrastructure was simulated using virtual machines with varying CPU sizes, memory amounts, and bandwidth and storage sizes. Dynamic workloads were generated by multiple cloud tasks that had different levels of computational requirements, priorities, and QoS constraints. The algorithms (DQ-Whale, PSO, ACO, and GA) were all implemented with the same workload and resources to facilitate a fair comparison. In simulation, task allocation and scheduling

decisions were continually analyzed depending on the makespan, throughput, response time, resource utilization, cost, and resource violation rate. The experiments were repeated with the same setup to evaluate the allocation efficiency and scheduling performance.

- Makespan: Total time needed to perform all tasks, and reducing makespan is a typical goal in resource allocation [24].
- Response time: The time it takes for a system to reply to a task request. Lower response times suggest more effective resource allocation [25].

$$Response\ time = completion\ time - task\ arrival\ time$$

- Throughput: Measures the number of jobs accomplished per unit of time. High throughput suggests efficient resource allocation [26].
- Resource Utilization: It tracks how effectively cloud resources (such as CPU, memory, and storage) are used. It represents the percentage of the resources accessible that are actively utilized. High utilization indicates efficient resource deployment but may result in overburden [27].

$$\text{Utilization rate} = \frac{Resource\ used}{Total\ Resource\ capacity} * 100\%$$

- Cost: The total cost taken for task allocation; lower values indicate cost effectiveness
- Resource violation rate: The percentage of time resources are overutilized or underutilized. A lower rate indicates better performance [28].

For more reliability in the experimental evaluation process, five different simulation runs of CloudSim were performed in each of the experiments with identical workload and resources of the five algorithms. All the same task characteristics, resources limitations and evaluation conditions were used for the DQ-Whale, PSO, ACO and GA to make a consistent comparison. The results are presented as mean ± standard deviation (n = 5 trials), and thus give information not only about the average performance in the trials, but also about the variation between the trials. Evaluated metrics: Makespan, throughput, response time, resource utilization, allocation cost, and resource violation rate. These results are therefore only observations of the algorithms based on a specific set of simulation conditions and should not be considered as statistically significant proof of the superiority of the algorithms.

Table II lists the performance measure values for the proposed Q-Whale, PSO, ACO, and GA algorithms. The makespan time for Q-Whale is 20 which is found to be low compared to all the other methods, indicating better performance in the hybrid Q-Whale algorithm. A value of 50 tasks/mts shows that a higher value in throughput indicates that the number of tasks completed per minute is higher in Q-Whale. The average time taken to respond to the task is low in the case of Q-whale. Q-Whale is cost-effective, and the resource violation rate shows only 2%, which is higher for Q-Whale compared to the contrasted methods PSO, ACO, and GA.

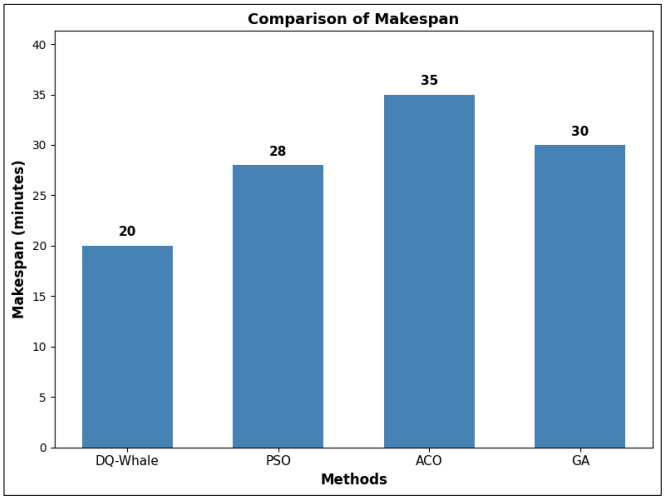

Fig. 3. Methods vs. makespan.

Fig. 3 shows a shorter makespan time of 20 minutes for the hybrid Q-Whale method and a maximum of 35 minutes for ACO. The nature of makespan time in the allocation of resources refers to how the overall completion time of a group of tasks (makespan) responds to or is influenced by various variables and methods in a resource allocation system. It is an important performance metric in CC and distributed systems since it has a direct impact on resource efficiency and system productivity.

TABLE II. PERFORMANCE MEASURES FOR RESOURCE ALLOCATION STRATEGIES

Methods/ Measures	Make span (mts)	Throughput (tasks/mts)	Response time (seconds/tasks)	Resource utilization (%)	Cost (units)	Resource violation Rate (%)
DQ-Whale (mts)	20	50	5	95	1000	2
PSO	28	45	8	88	1200	5
ACO	35	40	10	85	1500	7
GA	30	42	7	90	1300	4

Fig. 4 shows higher throughput for DQ-whale than for the PSO, ACO and GA methods. Throughput in resource allocation refers to how effectively a system can handle jobs over time, and it is an important performance indicator in CC, distributed systems, and task scheduling. Throughput influences a system's overall productivity and capacity to satisfy performance objectives.

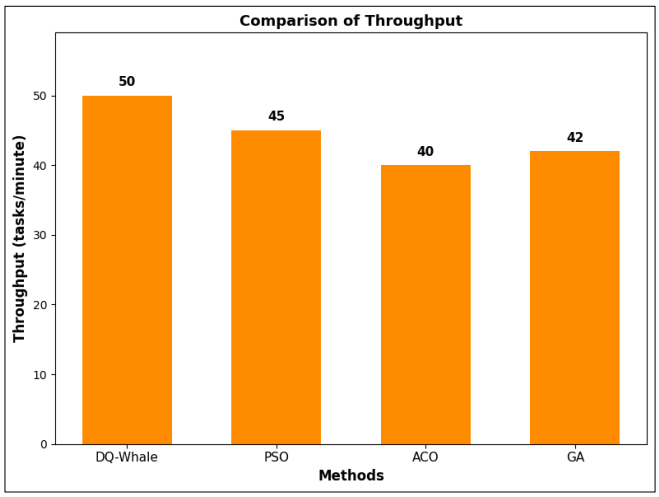

Fig. 4. Methods vs throughput.

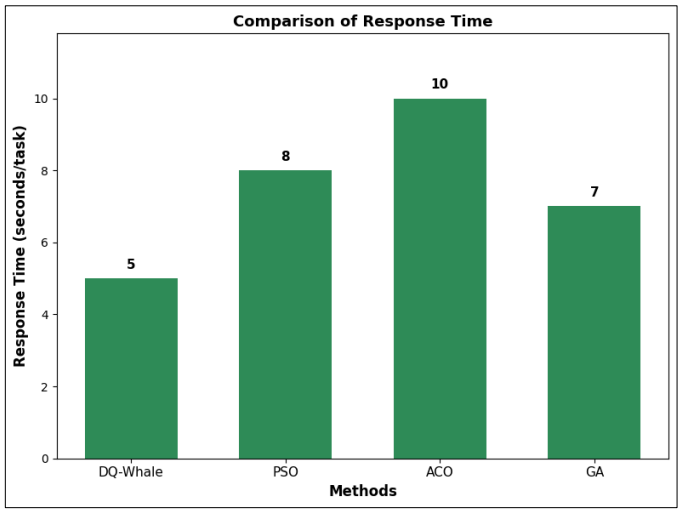

Fig. 5. Methods vs. response time.

Fig. 5 presents the response time for the proposed DQ-Whale method and other contrasted methods used for evaluation. The time taken to get a reply for tasks is low for the DQ-Whale method. The concept of reaction time in resource allocation relates to how soon a system can reply to and process a request or task once it has been received. It is an important performance indicator in computers, cloud services, and distributed systems since it impacts both user experience and system efficiency. Techniques that are adaptive to current network conditions, distribute load equitably, and properly prioritize jobs can assist in reducing reaction time.

As shown in Fig. 6, the resource utilization for DQ-Whale shows 95%, PSO as 88%, ACO as 85% and GA as 90% and is found to be high for hybrid DQ-Whale methods than the other methods. Resource utilization in resource allocation describes how efficiently and effectively the assets of a system (such as CPU, memory, bandwidth, and so on) are used to complete tasks. Proper resource use is critical for increasing performance, lowering expenses for operations, and ensuring that systems run efficiently.

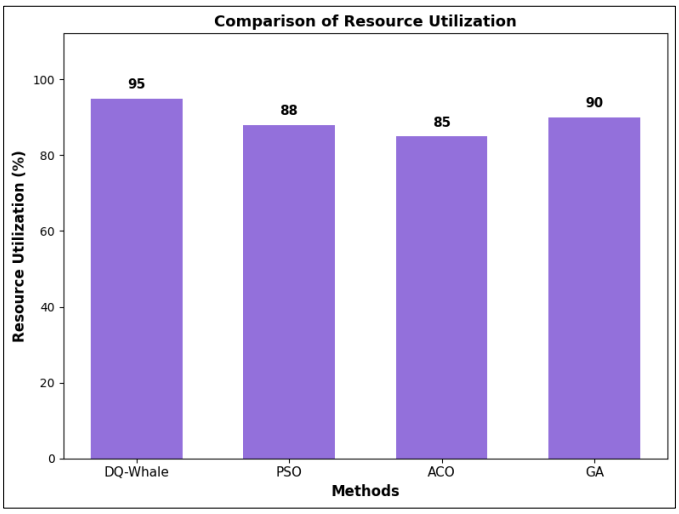

Fig. 6. Methods vs. resource utilization.

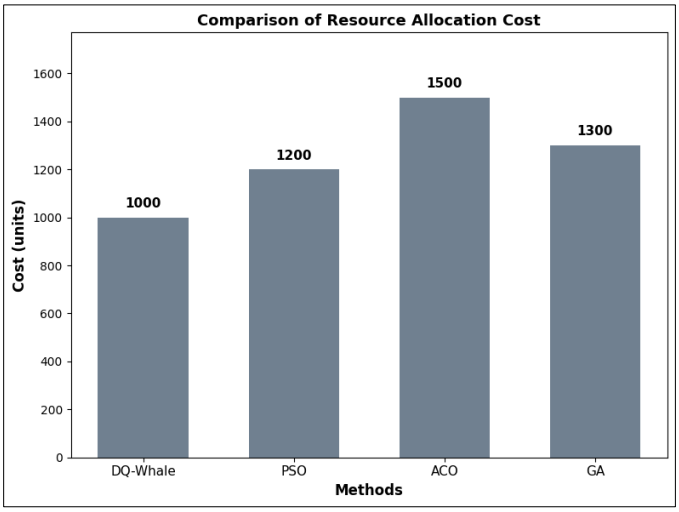

Fig. 7. Methods vs. cost.

Fig. 7 shows the decreased cost in units for proposed Q-whale method than the PSO, ACO and GA techniques. The cost in resource allocation relates to the numerous expenditures paid in order to properly use and manage computer resources inside a system. Cost concerns are critical in resource allocation because they impact decisions about infrastructure, optimizing performance, and overall system efficiency.

Fig. 8 shows a lower resource violation rate for DQ-Whale algorithm than for the PSO, ACO and GA strategies. In resource allocation, the resource violation rate refers to the frequency or possibility of resource consumption exceeding the allotted limitations or restrictions for a job or system. Resource violations can signal inefficiencies, future system overloads, or policy breaches; therefore, knowing this statistic is critical for improving resource allocation techniques. Q-Whale, PSO, ACO, and GA are examples of algorithms that aim to maximize throughput by efficiently distributing jobs to available resources. Their efficacy is determined by their ability to adapt to changing workloads, investigate the solution space, and strike a balance between exploration and exploitation.

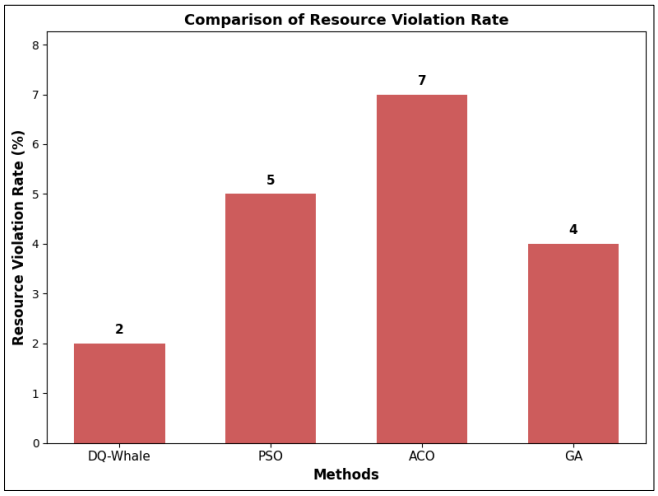

Fig. 8. Methods vs. resource violation rate.

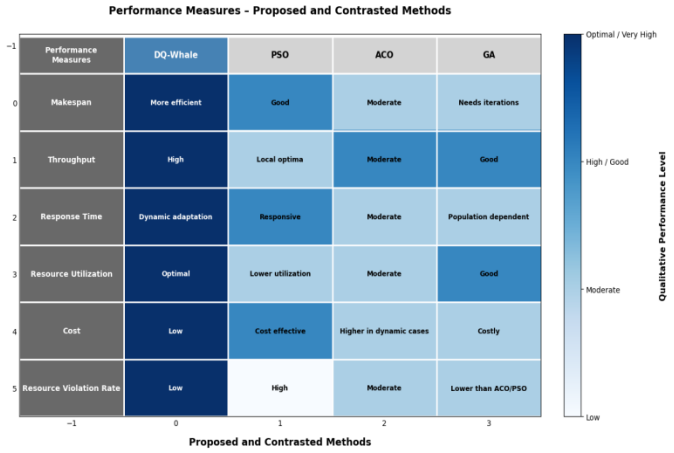

Fig. 9. Qualitative performance comparison of DQ-Whale, PSO, ACO, and GA across cloud resource allocation measures.

Fig. 9 is a comparison of DQ-Whale, PSO, ACO and GA in terms of six measures of cloud resource allocation. The makespan, throughput, latency, resource utilization, cost, and resource violation rate are good properties of DQ-Whale. It is adaptive in decision-making, which enables faster allocation and efficient utilization of resources with varying workloads. PSOs offer responsive allocation and can have local optima issues. ACO has moderate performance and convergence rate, especially in complex tasks. Good resource allocation is provided by GA, but it may need more iterations based on the complexity of the workload and population size. In general, the qualitative comparison shows the various features of the methods evaluated and the wide applicability of DQ-Whale for cloud resource management.

Table III points out that the main difference in methodology of DQ-Whale is the combination of Double Q-Learning with WOA, not the use of WOA. The reinforcement learning-WOA algorithms are also used as Q-Whale and SARSA-Whale, but with standard Q-Learning and SARSA, respectively. The innovation of DQ-Whale is that it employs two value estimators to diminish the potential overestimation in the process of action-value learning and keeps the WOA-based exploration and exploitation. The table also highlights that there is no numerical superiority of these methods over Q-Whale or SARSA-Whale for the experiments since the latter two methods were not tested with the same CloudSim configuration as described in the present experiments.

TABLE III. COMPARATIVE CHARACTERISTICS OF REINFORCEMENT-LEARNING–BASED HYBRID RESOURCE ALLOCATION APPROACHES

Performance/Methodological Aspect	DQ-Whale (Proposed)	Q-Whale	SARSA-Whale
Reinforcement learning strategy	Double Q-Learning	Q-Learning	SARSA
Value estimation	Two Q-tables	Single Q-table	Single action-value function
Action policy	Adaptive action selection using two value estimates	Q-value-based action selection	On-policy action selection
Overestimation control	Explicitly reduces Q-value overestimation	More susceptible to Q-value overestimation	Does not specifically employ Double Q-learning correction
Optimization mechanism	Whale Optimization Algorithm (WOA)	Whale Optimization Algorithm (WOA)	Whale Optimization Algorithm (WOA)
Exploration	Q-learning exploration combined with WOA exploration	Q-learning exploration combined with WOA	SARSA policy exploration combined with WOA
Exploitation	Double Q-value guidance with WOA exploitation	Q-value guidance with WOA exploitation	SARSA-based policy with WOA exploitation
Adaptation to changing states	High, through double-estimator learning	Adaptive through Q-value updates	Adaptive through on-policy updates
Allocation decision mechanism	State–action learning with reduced value-estimation bias	State–action learning	State–action–next-action learning
Main methodological characteristic	Combines bias-reduced reinforcement learning with population-based optimization	Combines conventional Q-learning with WOA	Combines on-policy SARSA learning with WOA
Expected computational consideration	Additional Q-table maintenance	Lower Q-learning memory requirement	Additional policy-transition evaluation
Direct comparability with present study	Evaluated under the proposed CloudSim configuration	Requires identical reimplementation and experimental conditions	Requires identical reimplementation and experimental conditions

There are still several issues in the current methods of allocation of cloud resources that can be improved in the future. A variety of studies have been conducted on algorithms in simulated and relatively controlled workloads, and this may not accurately reflect workloads in a highly dynamic cloud environment. Other approaches can have a tendency to

converge prematurely, suffer from local optima, have a higher computational load, and lack scalability with the number of tasks and resources. Moreover, few works have focused on multi-objective optimization that considers the trade-offs among the cost, energy consumption, latency, resource utilization, and QoS at the same time. Following researchers can consider adaptive hybrid algorithms with real world cloud workloads, online learning, multi objective optimization and distributed decision making in the future. Performance in edge-cloud and heterogeneous environments, as well as in case of workload uncertainty, failures of resources, and varying service level requirements, should be further studied.

V. CONCLUSION

The proposed Double Q-Learning–Whale Optimization (DQ-Whale) framework is an adaptive framework to allocate cloud resources using the decision-making process of the Double Q-Learning algorithm along with the exploration and exploitation ability of the Whale Optimization Algorithm (WOA). The experimental outcomes shown with CloudSim demonstrate good performance when compared with PSO, ACO, and GA for the simulation conditions with respect to the metrics, such as makespan, throughput, response time, resource utilization, cost and resource violation rate. But there are some drawbacks to this approach, DQ-Whale. Two Q-tables and a number of whale solutions increase the computational and memory cost; its performance might be dependent on the WOA parameters like the number of the whale population, the number of iterations and exploration–exploitation coefficients. Furthermore, the current assessment is based on a defined workload scale and simulated cloud environment, and thus the scalability, i.e., the ability to scale up to much larger workloads and significantly more heterogeneous infrastructures, has yet to be proven. In future, the numbers of tasks and virtual machines will be gradually increased to study scalability, parameter sensitivity, and ablation studies for the WOA, and computational overhead will be measured. Further experiments will investigate robustness against dynamic workloads and failures of resources, as well as changing QoS/SLA requirements. Repeated trials will also be performed together with the appropriate statistical significance tests for extensions of the multi-objective incorporating the energy consumption, cost, latency, and QoS.

***Abstract*—Generative artificial intelligence (GenAI) is creating new possibilities for data-informed decision-making in higher education, yet how it translates educational data into actionable decisions for different stakeholders remains undertheorised. This study reports a PRISMA-guided systematic review of 38 peer-reviewed empirical studies addressing three questions: what educational decisions GenAI supports in higher education (RQ1); how educational data and GenAI capabilities enable those decisions (RQ2); and what framework explains GenAI-driven educational decision-making (RQ3). Across the 38 studies, eight decision categories are identified inductively and organised into micro (learner-facing), meso (instructor and program), and macro (institutional) levels. Five enabling GenAI capabilities (natural language generation, behavioural and semantic analysis, multimodal processing, synthetic data generation, and conversational analytics) are mapped to each category. Synthesising these findings, this study proposes the GenAI-Driven Educational Decision-Making (GDEDM) framework: a four-layer model connecting educational data sources, GenAI capabilities, educational decision levels, and governance. The evidence reveals important cross-level patterns, divergences, and research gaps, exposing a critical governance gap between rapidly advancing GenAI capabilities and lagging institutional safeguards. The GDEDM framework offers researchers, practitioners, and policymakers a coherent, evidence-grounded basis for responsible GenAI deployment in higher education.**

Keywords*—Educational decision-making; generative artificial intelligence; higher education; data-informed decisions; large language models; systematic review

I. Introduction

Higher education institutions have invested in data-driven approaches to support a wide range of operational goals, including identifying at-risk students, personalising academic pathways, evaluating teaching effectiveness, and informing institutional resource allocation [1]. Yet translating educational data into timely, actionable decisions for the right stakeholders has remained a persistent challenge.

The emergence of generative artificial intelligence (GenAI), which encompasses large language models (LLMs) such as GPT-4, open-source models including Llama and ERNIE Bot, retrieval-augmented generation (RAG) systems, and generative adversarial networks (GANs), has significantly expanded what is technically possible in this space[2], [3], [4]. Unlike traditional machine learning approaches that predict or classify based on structured input, GenAI systems can generate natural language, synthesise insights from complex data, and support multimodal analysis [4]. These capabilities position GenAI as a bridge between educational data and decision-making, enabling systems to move beyond producing analytical outputs toward supporting educational decisions for students, instructors, and administrators [5], [6].

Early data-informed decision support in higher education relied on machine learning models for academic outcome prediction, including identifying at-risk students, forecasting grades, and modelling dropout risk [7]. These systems demonstrated the value of multi-feature models integrating behavioural, academic, and socioeconomic variables, but their outputs, such as probability scores and classification results, required considerable human expertise to translate into practical action.

The emergence of LLMs changed what AI-generated educational outputs look like: where predictive systems produce numbers, GenAI systems produce text, recommendations, and dialogues that function as decision artifacts in themselves [3]. Standards-based interoperable architectures combining multi-agent systems, xAPI trace collection, and LTI delivery have further shown how such GenAI decision outputs can be embedded within institutional learning management ecosystems at scale [2]. Yet despite this progress, the field lacks a comprehensive, decision-centred understanding of what GenAI supports across the full spectrum of higher education stakeholders and organisational levels.

Most existing reviews organise findings by model type, analytical technique, or isolated function (e.g., focusing on predictive tasks [8], dashboard applications [9], human-centered design [10], or explainability [11]) rather than by the educational decisions GenAI enables or the governance conditions required to make those decisions responsible. The present study addresses this gap through a systematic review of 38 empirical studies guided by three research questions:

- RQ1: What educational decisions are supported by GenAI in higher education?
- RQ2: How do educational data and GenAI capabilities support these decisions?
- RQ3: What framework can explain GenAI-driven educational decision-making in higher education?

The study makes three original contributions. First, a decision-centric synthesis of 38 empirical studies organised around eight inductively derived decision categories that provide an outcome-focused perspective on how GenAI supports educational decision-making. Second, a three-level decision taxonomy (micro, meso, and macro) grounded entirely in the empirical evidence. Third, the GDEDM framework: a four-layer, governance-inclusive model linking educational data sources, GenAI capabilities, educational decision levels, and responsible AI governance to support both scholarly understanding and institutional deployment.

II. Methodology

A. Search Strategy and Inclusion Criteria

Electronic searches were completed on March 6, 2026 across Scopus, Web of Science, and IEEE Xplore. The search string combined GenAI terms ("generative artificial intelligence" OR "Generative AI" OR "large language model*" OR LLM OR ChatGPT OR GPT) with educational data and decision terms ("learning analytics" OR "educational decision" OR "educational data mining" OR "student analytics") and higher education qualifiers ("higher education" OR universit* OR college OR "tertiary education" OR undergraduate* OR postgraduate*). Backward and forward citation snowballing supplemented database retrieval.

Studies were included if they: (IC1) employed a GenAI technique, such as a large language model or generative adversarial network; (IC2) applied it within a learning analytics (LA) workflow; (IC3) were conducted in a higher education context; (IC4) were published in a peer-reviewed journal or conference proceeding; and (IC5) reported original empirical research. A study was considered to involve educational data or LA workflow if it used learner-related data for analysis, modelling, or interpretation to inform understanding or support decision-making in an educational context [12], [13].

Following deduplication, 244 records were screened by title and abstract, of which 35 progressed to full-text review and 24 met the eligibility criteria. Citation snowballing identified 14 additional eligible studies, yielding a final corpus of 38 studies. The main exclusion reasons were absence of GenAI-enhanced LA (EC2, n = 121), non-empirical design (EC6, n = 51), absent GenAI application (EC1, n = 34), non-higher education setting (EC3, n = 7), and non-peer-reviewed source (EC4, n = 3). Some records met multiple criteria. Two reviewers independently screened the records, resolving disagreements through discussion and consensus, particularly regarding the presence of a learning analytics workflow and empirical evidence. The complete selection process is presented in Fig. 1.

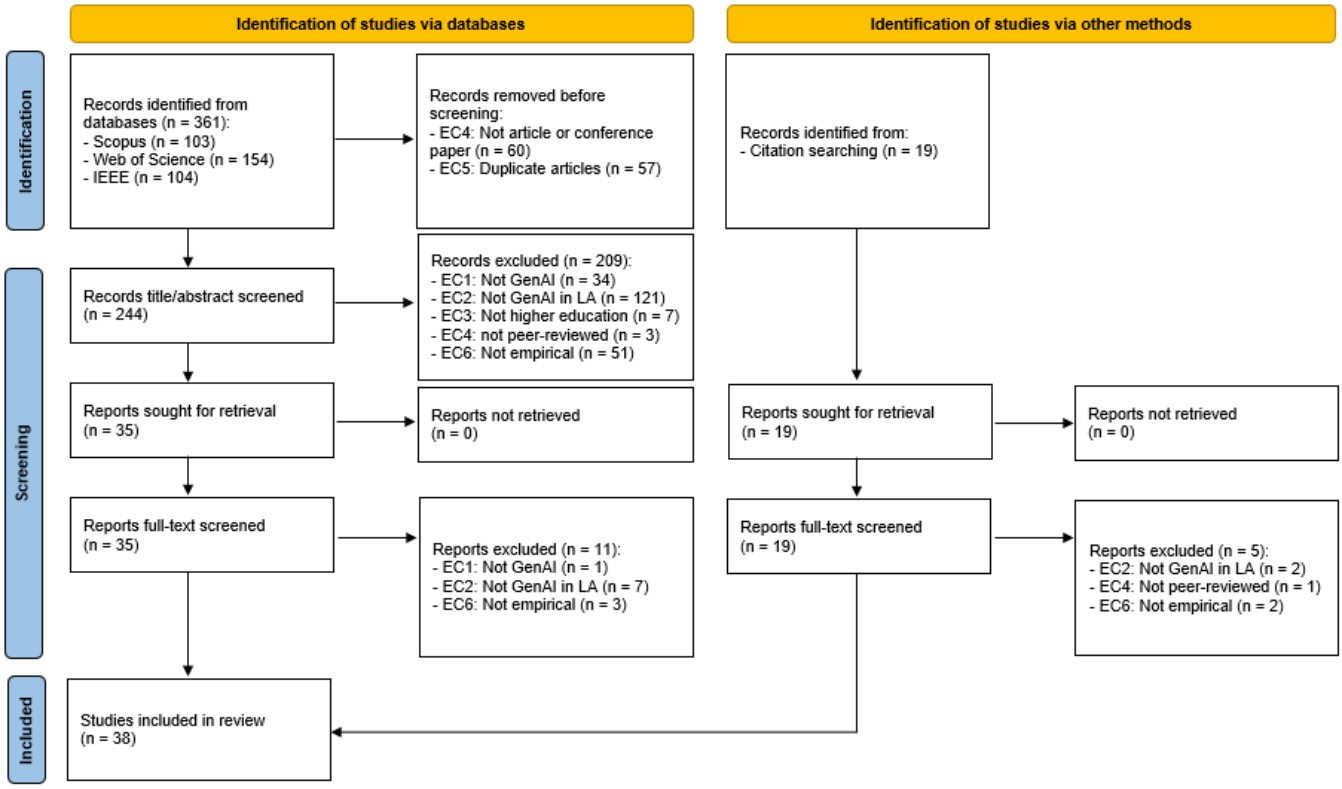

Fig. 1. PRISMA 2020 flow diagram of the article selection process.

B. Data Extraction and Analytical Approach

A structured extraction form captured the GenAI models, educational data sources, stakeholders served, educational decision types, and the GenAI capabilities enabling those decisions. The decision categories were derived inductively. For each study, the decision output was identified and grouped with functionally similar outputs across other studies. Categories were iteratively refined until each was conceptually distinct.

The eight resulting categories were then organised into three decision levels based on stakeholder scope and systemic consequence. Similarly, GenAI capabilities were identified by examining the primary role each GenAI technique performed within the learning analytics workflow. Functionally similar capabilities were grouped and iteratively refined into five overarching categories representing how GenAI enabled educational decision-making across the reviewed studies. Data extraction was performed by the first author and verified by a co-author, with discrepancies resolved through discussion.

Study quality was assessed using the Quality Assessment with Diverse Studies (QuADS) tool [14], a 13-item appraisal instrument suited to the heterogeneous mix of system evaluations, case studies, and user studies in the corpus. The first author appraised each included study across all 13 items, with total scores ranging from 24 to 38 out of 39, indicating generally adequate methodological quality. Quality appraisal informed the depth of synthesis and confidence in specific findings.

III. Results

A. Educational Decisions Supported by GenAI (RQ1)

The synthesis of the 38 studies identified eight educational decision categories supported by GenAI in higher education. These categories were organised into three decision levels: micro (learner-facing), meso (instructor- and program-level), and macro (institutional). Table I maps the decision categories to the GenAI technologies reported in the reviewed studies. Studies employing multiple technologies appear in more than one technology column. This section introduces the decision categories and associated technology patterns, while the subsequent RQ2 section examines how educational data and GenAI capabilities enable these decisions.

1) Micro-level decision categories: Four categories operate at the individual learner level. Feedback and Assessment Support is the most frequently studied category in the corpus (n = 8) and one of the broadest in technology coverage, supported by GPT-family models, open-source LLMs, unspecified LLMs, and RAG systems. This category focuses on assessment-related decisions through personalised feedback, formative assessment, rubric-based evaluation, and other feedback mechanisms that support learner improvement. The prominence of Feedback and Assessment Support may reflect the growing demand for scalable assessment support and personalised feedback in higher education.

TABLE I. Educational Decision Categories and Supporting GenAI Technologies

Decision Level	Decision Category	GPT-4/4o (ChatGPT)	Open-source LLMs (Llama, DeepSeek, ERNIE)	Unspecified LLMs	RAG Systems	Multimodal LLMs	GANs	Other Generative Models (TVAE, Gaussian Copula, DALL-E)	SQL / NL Query Agents	n
Micro	Feedback and Assessment Support	[15], [16], [17], [18], [19], [20]	[15]	[21]	[22]					8
	Learning Pathway Personalisation	[23], [24], [25], [26]			[22]	[23], [25]				5
	Academic Guidance and Advising	[6], [27], [28], [29]						[29]		4
Meso	Instructional Design Support	[25], [30], [31], [32]	[30], [31], [33]			[25]				5
	Collaborative Learning Analytics	[23], [34], [35]	[34], [36]	[37]		[38]				6
	Analytics Interpretation and Sensemaking	[5], [18], [39], [40]			[39], [41]	[39], [41]			[5], [40]	5
Macro	Early Warning and Intervention	[26], [42], [43], [44]	[45]				[46], [47]	[44]		7
	Strategic Institutional Planning	[5], [27], [29], [40], [48]	[45], [48]					[29]	[5], [40], [49]	7
	Total unique studies per technology	**27**	**8**	**2**	**3**	**5**	**2**	**3**	**3**	

2) Learning pathway personalisation (n = 5) supports decisions about adapting learning experiences, content sequencing, and instructional pathways to individual learner needs. Unlike Feedback and Assessment Support, which evaluates completed learning activities and provides formative feedback, this category focuses on adapting future learning experiences to individual learner needs. It exhibits considerable technological diversity, incorporating GPT-family models, RAG systems, and multimodal LLMs. Among the reviewed studies, it is the only micro-level category incorporating multimodal LLMs, suggesting growing interest in using diverse learner inputs to support personalised learning experiences.

Academic Guidance and Advising (n=4) supports decisions concerning course selection, programme planning, and academic progression. Whereas Learning Pathway Personalisation focuses on adaptation within learning environments, advising applications address broader academic choices that shape learners' educational trajectories. The category relies predominantly on GPT-family models, with only one study reporting the use of another generative approach (DALL-E) [29]. Its relatively narrow technology profile suggests that a limited range of GenAI approaches has been explored for advising applications in the reviewed studies. Collectively, the three micro-level categories demonstrate the central role of large language models in supporting learner-facing educational decisions, while highlighting distinct forms of decision support ranging from feedback to personalisation and advising.

3) Meso-level decision categories: Three categories serve instructors and program teams. Collaborative Learning Analytics (n=6) supports decisions related to monitoring, evaluating, and facilitating collaborative learning activities. It is the largest meso-level category and exhibits substantial technological diversity, combining GPT-family models, open-source LLMs, multimodal LLMs, and unspecified LLM-based agents across the reviewed studies. This technological diversity may reflect the complexity of collaborative learning, which often involves interactions captured through multiple modalities, including text, video, and behavioural traces [38].[38]

Instructional Design Support (n=5) supports curriculum improvement, course redesign, and instructional planning. Whereas Collaborative Learning Analytics focuses on understanding learner interactions, this category focuses on modifying the learning environment through evidence-informed instructional decisions. GPT-family models, open-source LLMs, and multimodal LLMs are the primary technologies reported in this category.

Analytics Interpretation and Sensemaking (n=5) focuses on supporting stakeholders in interpreting and acting on learning analytics outputs. Rather than generating new instructional recommendations, its primary role is to help stakeholders interpret and act upon existing analytical findings. Among the reviewed studies, it is the only meso-level category incorporating Structured Query Language (SQL) and natural-language query agents and one of only three categories employing Retrieval-Augmented Generation (RAG) systems. This category highlights the role of GenAI in bridging the gap between learning analytics outputs and their practical use in educational decision-making.

4) Macro-level decision categories: Two categories operate at the institutional level. Early Warning and Intervention (n = 7) supports decisions related to identifying at-risk students and initiating timely interventions through institution-wide monitoring and intervention strategies. It incorporates a distinctive combination of GPT-family models, graph neural networks (GNNs), GAN-based approaches, and other generative models, reflecting the use of complementary AI techniques to support institution-wide risk identification and intervention.

Strategic Institutional Planning (n = 7) supports institution-wide strategic and operational decisions related to student success, enrolment management, resource allocation, and organisational performance. Whereas Early Warning and Intervention focuses on identifying students requiring timely support, Strategic Institutional Planning focuses on informing broader institutional planning and management decisions. Its technology profile is characterised by GPT-family models, SQL-based systems, natural-language query agents, and other generative models, highlighting the role of conversational access to institutional data in supporting evidence-informed organisational decision-making.

Together, these macro-level categories illustrate how GenAI supports complementary forms of institutional decision-making: Early Warning and Intervention focuses on identifying and responding to student risk, whereas Strategic Institutional Planning supports broader organisational planning and management. Compared with the learner- and programme-focused categories, macro-level applications rely more heavily on institution-wide educational data and support decisions with broader organisational scope and consequences.

5) Technology distribution and structural gaps: GPT-family models appear across all eight decision categories and are employed across 27 of 38 studies, indicating their position as the dominant and most widely adopted technology in the current GenAI decision-support landscape. Open-source large language models (LLMs) (8 studies) appear across several educational decision categories, often serving as privacy-conscious or locally deployable alternatives to proprietary GPT-family models. Retrieval-Augmented Generation (RAG) systems and multimodal large language models (MLLMs) (3 and 5 studies, respectively) occupy more specialised roles, with RAG supporting knowledge-grounded applications and MLLMs concentrated in contexts involving multimodal educational data. Other generative models, including TVAE, Gaussian Copula, and DALL-E, appear in three studies, supporting synthetic data generation and complementary generative tasks. GAN-based models are identified within Early Warning and Intervention, where they enable privacy-preserving synthetic data generation for predictive learning analytics. SQL-based systems and natural-language query agents appear only in Analytics Interpretation and Sensemaking and Strategic Institutional Planning.

One notable structural gap in Table I is the absence of RAG-based systems within macro-level decision categories. Although RAG technologies are represented in several micro- and meso-level applications, none of the reviewed macro-level studies identified their use. This pattern suggests a potential area for future research, particularly given the growing importance of transparency, traceability, and evidence-informed decision-making in higher education institutions. Whether this absence reflects implementation challenges, research priorities, or the relative novelty of RAG technologies remains unclear from the current evidence base. The next section builds on these findings

by examining how educational data and GenAI capabilities support the identified educational decisions.

B. Data and GenAI Capabilities Enabling Educational Decisions (RQ2)

Table II summarises the educational data sources, stakeholders, and GenAI capabilities associated with each decision category across the 38 reviewed studies.

1) Mechanisms at the micro-level: Individual learner data form the foundation of all three micro-level decision categories. Across Feedback and Assessment Support, Learning Pathway Personalisation, and Academic Guidance and Advising, studies draw on assessment responses, LMS interaction logs, reflection texts, discussion forum contributions, student engagement data, and navigation histories to identify learner characteristics, engagement patterns, and learning needs. Natural language generation (NLG), often combined with conversational support mechanisms, translates these insights into personalised feedback, recommendations, adaptive guidance, and other learner-facing outputs that support educational decision-making.

TABLE II. DECISION-LEVEL MAPPING: STAKEHOLDERS, DATA SOURCES, GENAI CAPABILITIES, AND STUDIES

Decision Level	Decision Category	Stakeholder(s)	Educational Data Source	GenAI Capability	Studies
Micro (Learner-Facing)	Feedback and Assessment Support	Students, Instructors	Student handwritten notes, writing assignments, open-ended responses, discussion forum posts, online activity data, LMS interaction logs, feedback trace logs	NLG for personalised and scalable feedback; RAG-grounded formative assessment generation; LLM rubric interpretation and tag-based recommendation; dialogue-based scaffolding of analytics feedback	[15], [16], [17], [18], [19], [20], [21], [22]
	Learning Pathway Personalisation	Students, Instructors	Multimodal data (speech, facial expression, text), discussion forum posts, student engagement and behavioural data, large-scale MOOC datasets, real-time navigation and activity logs	Adaptive scaffolding generation from real-time trace data; multimodal chain-of-thought pathway planning; RAG-guided learning objective alignment; NLP-based engagement analysis to support adaptive personalisation	[22], [23], [24], [25], [26]
	Academic Guidance and Advising	Students, Academic advisors	Student course enrolment data, advising survey responses, advisor evaluation records, focus group transcripts, AI-assisted learning interaction data	Profile-aware NLG course recommendation; LLM rule-based course matching; GPT-based major selection advising with advisor comparison; qualitative thematic analysis for student perspective understanding	[6], [27], [28], [29]
Meso (instructor/ Program)	Instructional Design Support	Instructors, Curriculum designers	Multimodal classroom data (speech, facial expression, text), question bank datasets, student reflective writing, student interaction and behavioural trace logs, course data	Multimodal LLM analysis for iterative course redesign; LLM-based automated learning objective labeling; reflection analysis for instructor insights; ERNIE Bot-based human-AI collaboration analysis; LLM co-creation of instructional materials	[25], [30], [31], [32], [33]
	Collaborative Learning Analytics	Instructors, Researchers, Administrators	Discussion forum posts, asynchronous peer discussion datasets, mixed reality interaction logs, student reflection texts, video recordings of collaborative tasks, multimodal data (eye-tracking, interaction logs, dialogue)	LLM-based cognitive presence detection and summarisation; automated SSRL phase coding; process mining of knowledge construction sequences; grounded prompt engineering for deductive coding (GROPROE); multimodal LLM posture annotation; help-seeking process analysis	[23], [34], [35], [36], [37], [38]
	Analytics Interpretation and Sensemaking	Students, Instructors, Administrators	Online learning activity logs and peer review data, descriptive LA task datasets, LA dashboard interaction datasets, student reflection and GenAI assistant interaction logs	GPT-4o + RAG conversational agents for dashboard interpretation; NL-based dashboard and visualisation generation; ChatGPT code interpreter for descriptive analytics support; multimodal GenAI + RAG scaffolding for visual analytics comprehension; dialogue-based scaffolding of analytics feedback	[5], [18], [39], [40], [41]
Macro (Institutional)	Early Warning and Intervention	Instructors, Advisors, Academic support staff	Campus card transaction and exam score data, student engagement and behavioural data, lecture slides and assessment records, ChatGPT interaction logs, e-book interaction logs including reading time and page interactions	LLM + GNN graph embedding for multi-source behavioural analysis and risk detection; GPT-4 + NLP for engagement-driven predictive insights; LLM-driven ontology extraction and knowledge graph construction for performance prediction; ChatGPT-based feature extraction from conversation logs; LLM agent for e-book interaction factor analysis	[26], [42], [43], [44], [45]
	Strategic Institutional Planning	Administrators, Institutional researchers	Retention data, GPA trends and graduation rate records, campus card and exam score data, student survey responses, focus group transcripts, online learning datasets, descriptive LA task datasets, AI-assisted learning interaction data	Automated SQL query generation for institutional data access; LLM + GNN multi-source report generation; LLM-based sentiment analysis and summarisation of student surveys; GPT-4 + Claude qualitative thematic coding; GPT-4o NL dashboard generation and visualisation; ChatGPT code interpreter for non-expert analytics support; GPT-Turbo generative learning insights	[5], [27], [29], [40], [45], [48], [49]

Retrieval-Augmented Generation (RAG) strengthens several micro-level applications by grounding outputs in domain-specific educational content, including course rubrics, learning objectives, and disciplinary knowledge, thereby improving factual consistency and contextual relevance [22], [39]. Studies employing RAG generally emphasise grounding mechanisms as a means of improving the reliability and contextual relevance of generated outputs. A complementary quality-assurance pattern is also evident. Studies without RAG frequently incorporate instructor review between GenAI output generation and learner delivery (Xavier et al., 2025; Lekan & Pardos, 2025), whereas RAG-enabled systems are more often implemented with higher levels of automation. This pattern suggests that both RAG and human oversight may serve as complementary mechanisms for enhancing output quality and reliability at the micro level.

Despite relying on similar GenAI technologies, the micro-level decision categories differ in the learner data they use and the decisions they support. Feedback and Assessment Support focuses on assessment-related decisions through personalised feedback, formative assessment, rubric interpretation, and other feedback mechanisms that support learner improvement. In contrast, Learning Pathway Personalisation uses behavioural, engagement, and multimodal learner data to adapt future learning experiences, content sequencing, and instructional pathways to individual learner needs. Academic Guidance and Advising combines learner records, advising information, and student perspectives to support course selection, programme planning, and academic progression. These differences reflect distinct educational objectives and decision contexts despite their reliance on similar underlying GenAI capabilities. Treating them as a single analytical category would therefore obscure important differences in the learner data, decision processes, and evaluation approaches associated with each category.

2) Mechanisms at the meso-level: The analytical challenge at the meso level shifts from individual personalisation to cohort-level pattern detection. Collaborative Learning Analytics draws on one of the widest ranges of educational data in the corpus, including discussion forum posts, video recordings, group activity logs, student reflections, and multimodal interaction data. Across the reviewed studies, multimodal LLM annotation and process mining are used to extract meaningful pedagogical signals from these collaborative interactions [37], [38], [50]. A nuanced distinction exists between behavioural coding (classifying what interaction types occurred) and process mining (mapping temporal sequences and dynamics of collaboration): both are present in the evidence base, but few studies combine them. The limited integration of these two analytical modes suggests an opportunity for richer and more actionable collaborative decision support.[37], [38], [50]

Instructional Design Support uses aggregated cohort data to generate curriculum and instructional recommendations, typically through a pattern analysis stage that informs subsequent NLG [30], [31]. GenAI in this category identifies which learning objectives, topics, or instructional sequences are associated with persistent underperformance, then generates specific redesign suggestions for instructors.

Analytics Interpretation and Sensemaking relies on a highly diverse capability set, combining natural-language querying, RAG-augmented explanation, and dialogue-based scaffolding to support stakeholders with varying levels of technical expertise, from non-technical administrators querying databases [40] to students interpreting their own performance patterns [18]. Unlike the other meso-level categories, the primary contribution of this category lies not in generating new analytical insights but in enabling stakeholders to understand and act upon existing learning analytics through conversational and context-aware interactions.

Together, the three meso-level categories illustrate complementary mechanisms through which GenAI supports instructor- and programme-level decision-making. Collaborative Learning Analytics focuses on extracting pedagogical insights from complex interaction data, Instructional Design Support translates cohort-level patterns into curriculum improvements, and Analytics Interpretation and Sensemaking makes analytical outputs more accessible to stakeholders through natural-language interaction and contextual explanation. These differences demonstrate that GenAI supports meso-level decisions not only by generating new insights but also by improving stakeholders' ability to interpret and act on existing learning analytics.

3) Mechanisms at the macro-level: At the macro level, educational decisions are informed by institution-wide educational data, including student information systems, retention records, survey responses, campus card transactions, and longitudinal behavioural data. These broader and more integrated data sources enable GenAI capabilities that support institution-wide risk identification, strategic planning, and organisational decision-making.

Early Warning and Intervention combines multiple educational data sources to identify students at risk of academic failure or disengagement. The reviewed studies employ complementary GenAI technologies, including graph neural networks (GNNs), large language models (LLMs), and GAN-based synthetic data generation. GNNs are used to model the relational and temporal structure of student behavioural data, while LLMs translate analytical outputs into natural-language risk summaries and intervention recommendations [26], [42], [45]. GAN-based approaches generate privacy-preserving synthetic educational data that support the development, evaluation, and validation of predictive learning analytics models when authentic educational data are limited [46], [47]. Together, these complementary capabilities strengthen institution-wide risk identification and intervention.

Strategic Institutional Planning draws on institutional datasets, including graduation records, retention data, survey responses, and administrative databases, to support strategic and operational decisions. Natural-language querying and SQL-based interfaces improve access to institutional analytics by enabling administrators to interrogate complex data through conversational interaction, thereby supporting evidence-informed planning and decision-making [5], [40], [49].

4) Cross-level patterns, contradictions, and research gaps: Across the reviewed studies, three cross-level patterns emerge. First, learner-generated educational data, including LMS interaction logs, assessment records, and behavioural traces, form the primary foundation for GenAI-supported educational decisions across all three levels, although multimodal and institutional data become increasingly important at the meso and macro levels. This pattern reflects the growing maturity of educational data infrastructures supporting GenAI applications in higher education [2].

Second, human oversight varies across decision levels. At the micro level, studies report both augmentation approaches, where instructors review GenAI-generated outputs before learner delivery [6], [16], and automation approaches, where outputs are delivered with minimal human intervention [17], [20]. In contrast, macro-level applications consistently position institutional stakeholders as the primary decision-makers, with GenAI supporting rather than replacing institutional judgment [5], [40], [49].

Third, GenAI capability selection appears to depend on the educational task. Studies comparing proprietary GPT-family and open-source LLMs for learner-facing natural language generation generally report stronger performance for GPT-family models in the reviewed studies for feedback and advising tasks [6], [15]. In contrast, studies employing open-source LLMs for behavioural coding and analytical tasks report comparable performance while highlighting advantages in cost, privacy, and local deployment [34], [35], [36]. At the macro level, complementary techniques such as GNNs and GANs extend GenAI capabilities by supporting relational modelling and privacy-preserving synthetic data generation for predictive learning analytics [42], [46], [47]

Among the research gaps identified across the reviewed studies, limited evidence on the long-term effectiveness of GenAI-supported educational decisions and the relatively limited attention to responsible AI governance emerged as particularly important. Only one study [17] evaluated outcomes across multiple semesters, while fairness, transparency, and accountability were seldom addressed despite the increasing use of GenAI in educational decision-making. These cross-level patterns and research gaps informed the development of the GDEDM framework presented in the following section.

C. The GDEDM Framework (RQ3)

The findings from RQ1 and RQ2 reveal a consistent structural logic across the evidence: educational data provide the foundation for GenAI capabilities, which enable educational decisions operating within responsible AI governance. The GDEDM (Generative AI-Driven Educational Decision-Making) framework formalises this logic as four interconnected layers, illustrated in Fig. 2. Unlike frameworks that describe analytical workflows or system architectures, GDEDM is organised around the conceptual relationships between educational data, GenAI capabilities, educational decisions, and responsible AI governance, making it applicable as both a scholarly explanatory model and a practical reference for institutional GenAI adoption.

1) Layer 1 – Educational data sources: Layer 1 comprises the educational data that underpin all GenAI-supported educational decisions. The framework distinguishes two complementary data sources: learner-generated data, representing learning activities, assessment, and behavioural traces, and institutional data, comprising academic and administrative records that support institution-wide decision-making. The quality and representativeness of these data determine which educational decisions can be supported and how reliably they can be informed. Richer multimodal data, including classroom recordings, eye-tracking, and posture traces, expand decision support to collaborative and immersive learning contexts [37], [38], [50] while introducing additional privacy obligations and processing complexity. Consequently, data quality is fundamental to trustworthy decision-making.[37], [38], [50]

2) Layer 2 — GenAI capabilities: Layer 2 comprises five complementary GenAI capabilities: Natural Language Generation, Behavioural and Semantic Analysis, Multimodal Processing, Conversational Analytics, and Synthetic Data Generation. Natural Language Generation produces personalised feedback, recommendations, and other educational outputs; Behavioural and Semantic Analysis extracts meaningful patterns and insights from learner interactions and educational data; Multimodal Processing integrates and interprets heterogeneous educational data, including text, speech, video, and behavioural traces; Conversational Analytics enables natural-language interaction with learning analytics and institutional data, supporting query generation, dashboard visualisation, and contextual interpretation; and Synthetic Data Generation creates privacy-preserving datasets for developing, evaluating, and validating AI-supported educational decision systems when authentic educational data are limited.

Retrieval-Augmented Generation (RAG) functions as a cross-cutting quality mechanism within Layer 2 by grounding LLM outputs in verified educational content, thereby improving factual consistency and trustworthiness [22], [39]. Among the reviewed studies, RAG was not applied in macro-level decision support, representing an opportunity to enhance the transparency and reliability of institutional GenAI applications.

3) Layer 3 — Educational decisions: Layer 3 organises the eight evidence-derived educational decision categories into three decision levels. The micro level comprises learner-facing decisions (Feedback and Assessment Support, Learning Pathway Personalisation, and Academic Guidance and Advising); the meso level supports instructor- and programme-level decisions (Instructional Design Support, Collaborative Learning Analytics, and Analytics Interpretation and Sensemaking); and the macro level supports institution-wide decisions (Early Warning and Intervention and Strategic Institutional Planning).

Together, these levels represent a progression from individual learner support to organisational decision-making, with increasing stakeholder responsibility and governance requirements. This progression provides a practical roadmap for institutional GenAI adoption, enabling lower-risk learner-facing applications before extending deployment to institution-wide decision support requiring more comprehensive governance.

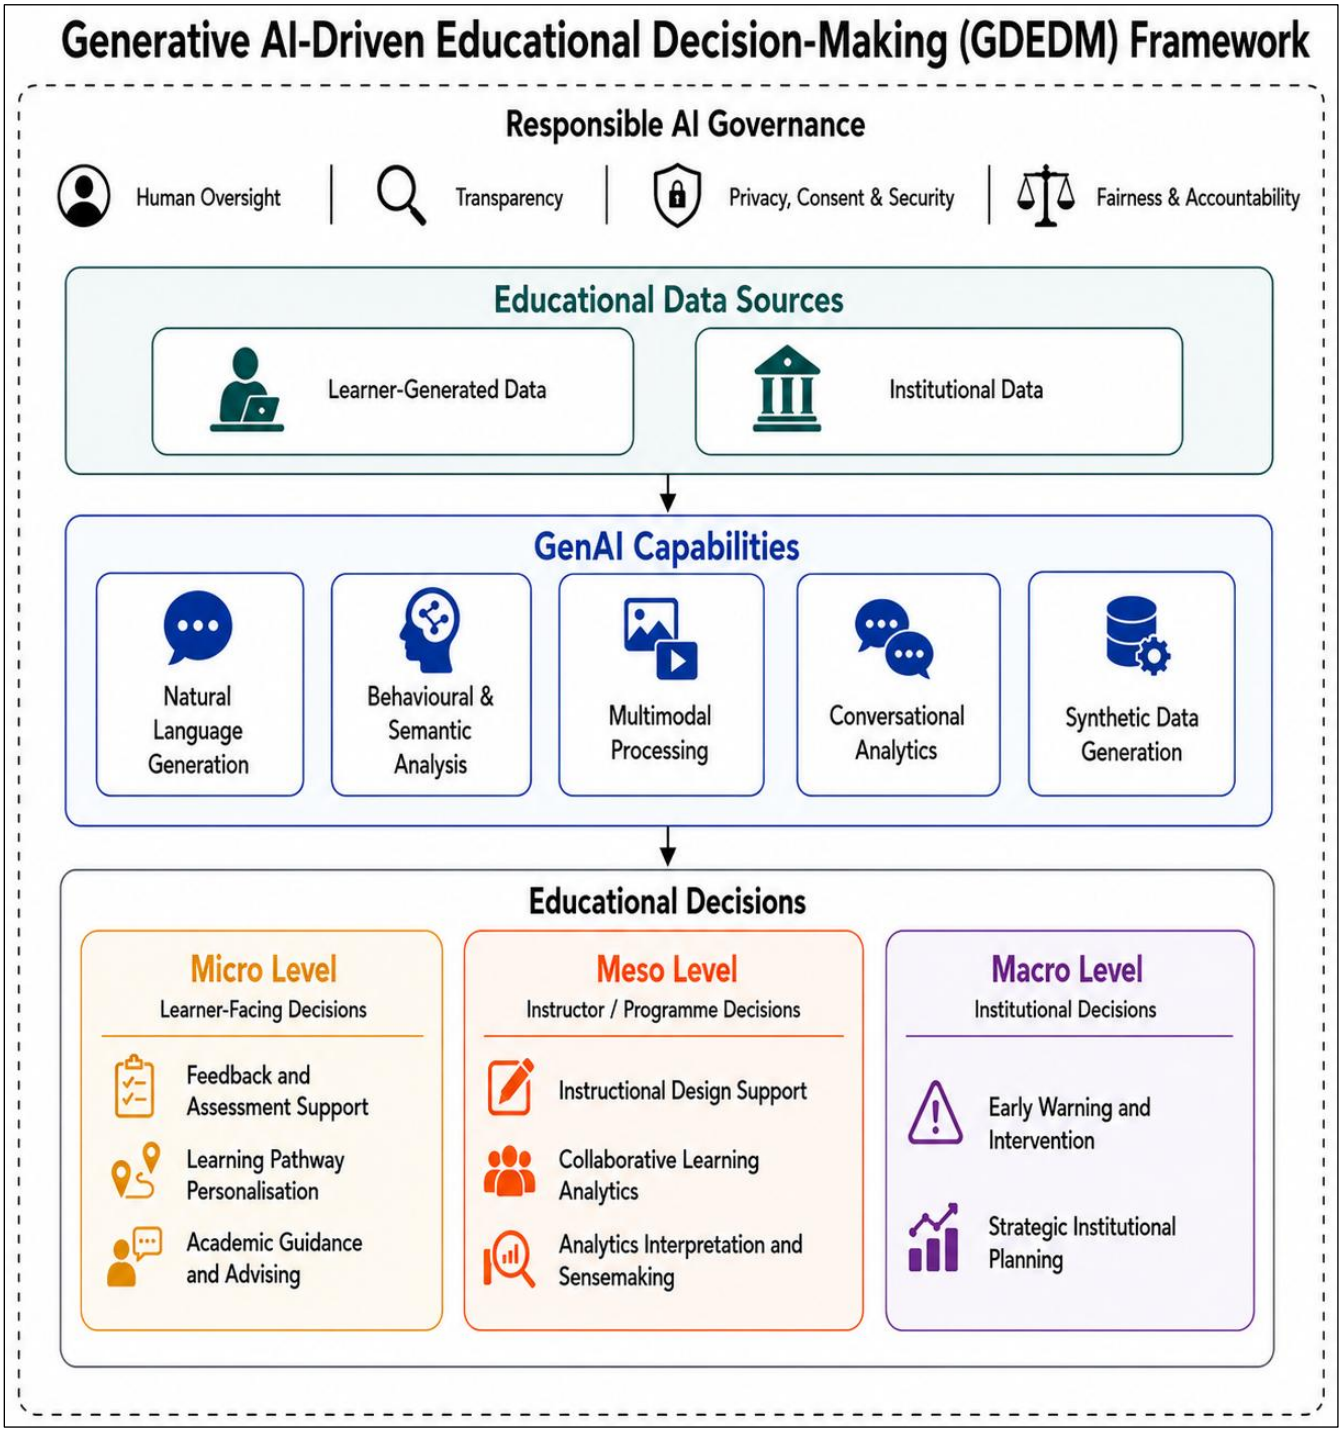

Fig. 2. The GDEDM framework.

4) Layer 4 — Responsible AI governance: Governance is represented as an overarching layer surrounding the framework, ensuring that responsible AI principles apply across educational data, GenAI capabilities, and educational decisions. The framework highlights four governance principles: Human Oversight, Transparency, Privacy, Consent and Security, and Fairness and Accountability. Human Oversight ensures meaningful human authority over consequential educational decisions. Transparency supports explainable GenAI outputs. Privacy, Consent and Security govern the responsible

management of educational data, while Fairness and Accountability require institutions to monitor bias and maintain clear responsibility for GenAI-supported decisions. Together, these principles embed governance across all layers of the framework rather than treating it as a separate implementation stage.

The review also highlights several governance priorities for institutional GenAI adoption. None of the reviewed studies systematically evaluated whether GenAI-supported decisions produced differential outcomes across student demographic groups despite well-established concerns regarding algorithmic bias [3], [7]. Consequently, the GDEDM framework emphasises fairness and accountability through equity auditing, particularly for macro-level decisions affecting institutional planning, resource allocation, and student success. Responsible deployment also requires transparency, informed consent, data minimisation, human oversight, and clearly defined accountability. Together, these governance principles support trustworthy GenAI-enabled educational decision-making.

IV. Discussion

The GDEDM framework and its evidential foundations offer three broader insights into the adoption of GenAI for educational decision-making in higher education.

First, organising the literature around educational decisions rather than GenAI technologies reveals research priorities that are less apparent in technology-centred reviews. The eight educational decision categories show that evidence is strongest for Feedback and Assessment Support (n = 8), whereas Academic Guidance and Advising (n = 4) and Instructional Design Support (n = 5) remain comparatively underexplored despite their importance for improving student success and teaching quality. These findings suggest that future research should extend beyond feedback generation to investigate how GenAI can support a broader range of educational decisions across learners, instructors, and institutions.

Second, the review identifies a governance gap between rapidly advancing GenAI capabilities and institutional safeguards. GenAI systems are increasingly being deployed to support decisions at the micro, meso, and macro levels, yet relatively few studies explicitly address governance mechanisms such as transparency, human oversight, privacy, or fairness. The GDEDM framework therefore positions responsible AI governance as a cross-cutting layer, demonstrating that governance should accompany educational data, GenAI capabilities, and educational decisions rather than being considered only after deployment.

Third, the review highlights explainability as a critical requirement for trustworthy educational decision-making. At the micro level, GenAI frequently delivers personalised feedback, recommendations, and guidance directly to learners. However, students and educators may be unable to judge whether these outputs are accurate, appropriate, or free from bias. Developing explainable GenAI systems that provide understandable justifications for educational recommendations therefore represents an important direction for future research and practical implementation.

These findings should, however, be considered in light of several limitations. The search was restricted to three databases and English-language publications, potentially introducing coverage and publication bias. In addition, the literature search was completed in March 2026; therefore, studies published thereafter were not included. Although grounded in 38 empirical studies, the GDEDM framework has not yet been independently validated through expert assessment or real-world institutional application.

V. Conclusion

This study presented a PRISMA-guided systematic review of 38 empirical studies examining how GenAI supports educational decision-making in higher education. For RQ1, eight educational decision categories were identified and organised into micro-, meso-, and macro-level decisions. Feedback and Assessment Support (n = 8), Early Warning and Intervention (n = 7), and Strategic Institutional Planning (n = 7) were the most frequently represented categories, whereas Academic Guidance and Advising (n = 4) remained comparatively underexplored.

For RQ2, five GenAI capability categories were identified, demonstrating how natural language generation, behavioural and semantic analysis, multimodal processing, conversational analytics, and synthetic data generation enable different forms of educational decision-making across stakeholders and institutional contexts. For RQ3, this study proposed the GenAI-Driven Educational Decision-Making (GDEDM) framework, a four-layer model connecting educational data sources, GenAI capabilities, educational decisions, and responsible AI governance. The framework provides both a conceptual explanation of GenAI-supported educational decision-making and a basis for future research and evaluation of responsible institutional adoption.

The review identifies three priorities for future research. First, longitudinal and multi-institutional studies are needed to evaluate the long-term effectiveness of GenAI-supported educational decisions. Second, systematic evaluation of fairness and accountability, including equity auditing, is required to support trustworthy institutional deployment. Third, explainable GenAI approaches should be developed to improve transparency and stakeholder trust across learner-, instructor-, and institution-facing applications. Overall, the GDEDM framework provides an evidence-based model that integrates educational data, GenAI capabilities, educational decisions, and responsible AI governance to support responsible GenAI adoption in higher education, thereby contributing to the advancement of inclusive and high-quality higher education in support of Sustainable Development Goal 4 (SDG 4: Quality Education).

***Abstract*—With the emergence of smart homes based on the Internet of Things, network-based attacks have become more prevalent and require effective and lightweight intrusion detection (ID). In this study, a Correlation-Aware Hybrid Feature Selection (CAHFS) framework for smart home IDS is proposed. The proposed approach fuses correlation analysis and Mutual Information (MI) and Random Forest (RF) feature importance to eliminate redundant and less important features and keep only those features that contribute most to the classification. To evaluate the different feature-selection strategies, four machine-learning models were tested: Logistic Regression (LR), Decision Tree (DT), Random Forest (RF) and HistGradientBoosting. Among the classifiers, HistGradientBoosting provides the most stable results out of the assessed models. The proposed CAHFS feature set, using only 16 features, yielded 91% accuracy, 91% precision, 90% recall, 90% F1-score, and a ROC-AUC of 0.96. It was also able to attain an accuracy level of about 95% specificity with an overall error rate of 8.9%, which provides a good balance between detecting the attacks and avoiding false alarms. The comparison with other feature-selection methods demonstrated that CAHFS managed to decrease the number of features from 22 to 16, with the same or similar classification results. Overall, the findings indicate that CAHFS can offer a more compact and informative feature set to be used in machine-learning-based intrusion detection in smart-home networks, which may benefit networks with limited computational resources.**

***Keywords*—Smart home; intrusion detection; machine learning-feature representation; correlation-aware hybrid feature selection**

I. Introduction

The Internet of Things (IoT) has transformed the way people today live in their homes by bringing many different types of devices together, from cameras to sensors, smart devices to lighting systems, voice assistants to access-control systems. They often use communication technologies like Wi-Fi, Bluetooth, and Zigbee, and may even connect with cloud-based services and mobile apps [1][2]. This connectivity is very convenient, automated, and accessible, but also increases security threats with the number of connected points that can be attacked [3][4]. Smart home systems can be targeted by attacks like unauthorized access, information theft, device manipulation, and network reconnaissance, which compromise their confidentiality, integrity, and availability. Fig. 1 illustrates how connected IoT devices, communication technologies, automation, and remote services provide convenience and accessibility while creating a larger networked environment that requires effective security monitoring.

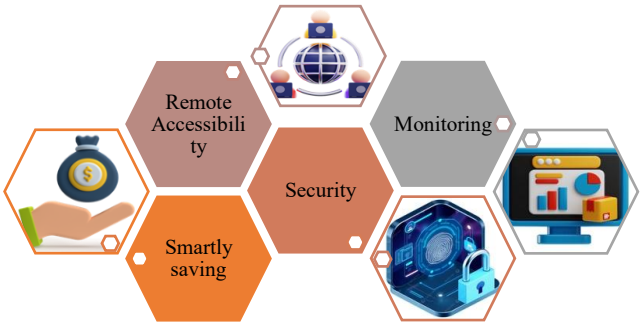

Fig. 1. Key benefits of smart home system.

A smart home can be viewed from a security perspective as a continual process that involves devices creating and sharing data, network traffic gathering and tracking, suspicious activity analysis, and necessary security measures. In the process, an Intrusion Detection System (IDS) is placed to monitor network traffic and detect whether it is normal traffic or if a possible attack is being made. In the context of smart homes, the IDS becomes even more crucial due to the wide range of capabilities and communication methods among IoT devices. A lot of these devices are also constrained in their computing and storage capacity and connected to the network for extended periods of time. Thus, an effective IDS should be able to detect the attacks efficiently without adding unnecessary complexity [5][6].

Fig. 2. Functional benefits of intrusion detection system in smart-home environment.

Fig. 2 summarizes the role of IDS in monitoring network traffic, identifying suspicious activities, distinguishing legitimate and malicious behavior, and supporting timely security response.

Traditional IDS methods rely on signature- and rule-based detection, which are able to detect attacks that have a known pattern. However, they may not be as effective when facing new or changed attack behaviors. Machine learning (ML) methods have therefore received a lot of attention in terms of IoT intrusion detection, as they can learn patterns from network traffic and then identify whether the traffic is legitimate or malicious, based on the patterns learned. In the past, various IDS configurations have been studied, such as centralized, distributed, edge, and fog systems, as well as various machine learning and deep learning algorithms [7][8].

Even with these advances, selecting an appropriate classifier is just part of the intrusion detection problem. The effectiveness and efficiency of the resulting detection model are also directly affected by the representation of the input data. Features in smart home traffic datasets may include many similar features, and there may be others that do not help to differentiate between legitimate traffic and attack. Redundant variables or variables that contribute only a marginal amount of information to the learning problem can make the problem unnecessarily complex and may lead to the creation of an unnecessarily high-dimensional model. Removing features due to correlation can also remove variables that carry useful information for attack classification, on the other hand. Another limitation may arise when evaluating feature relevance based on a single criterion, as different approaches may focus on different aspects of the usefulness of a feature. This shows that there is a need for a feature selection method that takes into account feature redundancy and usefulness to the intrusion detection problem [9].

To address the issue, this study Correlation-Aware Hybrid Feature Selection (CAHFS) model for smart home intrusion detection. The proposed method is intended to remove unnecessary and repetitive features from network traffic data while keeping the information needed to distinguish between normal and attack activity. To assess its effectiveness, the selected feature set is tested with four machine learning models, namely LogisticRegression, DecisionTree, RandomForest, and HistGradientBoosting. The comparison is based on standard classification metrics and error detection analysis using an independent test set.

The study does not propose a new classification algorithm; rather, it focuses on improving the input representation through a correlation-aware hybrid feature selection strategy. The proposed CAHFS model jointly considers feature redundancy and predictive relevance by combining correlation analysis, mutual information, and random forest importance. This provides a broader assessment of feature usefulness than relying on a single selection criterion. The resulting compact feature representation is subsequently evaluated using ML classifiers to determine whether dimensionality reduction can be achieved without substantially compromising the intrusion detection system.

To systematically evaluate the effectiveness of the proposed model, this study addresses the following Research Questions (RQ): -

RQ-1: How does the proposed CAHFS feature representation affect the performance of various ML classifiers for smart-home intrusion detection compared with alternative feature selection strategies?

RQ-2: Which ML classifier provides the most effective balance between detection performance and classification errors when using the proposed CAHFS feature representation?

The following are the main contributions of this study:

- A Correlation-Aware Hybrid Feature Selection (CAHFS) framework is proposed for a smart home intrusion detection system by combining Correlation-based redundancy analysis with complementary mutual information and random forest importance.
- The proposed approach reduces the original 22 features to 16 selected features, providing more compact input space while retaining discriminative information for intrusion detection.
- Four ML classifiers, namely (Logistic Regression, Decision Tree, Random Forest, and HistGradientBoosting), are systematically evaluated using multiple feature selection strategies under separate validation and independent test protocols.
- The classifiers are further assessed using classification metrics, confusion matrix, ROC AUC, and precision-recall analysis to examine both overall predictive performance and class-wise detection behavior.

The remainder of the study is divided into four sections. In Section II, the key research gap was identified. In Section III, the overall methodology adopted was discussed. In Section IV, the interpretation of the experimental analysis was defined and discussed. Finally, in Section V, necessary future directions and research conclusions were discussed.

II. Literature Review

Previous studies have shown that machine learning algorithms can enhance intrusion detection in IoT contexts by detecting network traffic patterns when they are normal or abnormal. Random Forest, XGBoost, and LightGBM prove to be good detection performance for ensemble methods. This study provides a comparison of these methods and presents improved efficiency, specifically 99.92% accuracy overall for the proposed LGB-IDS method [10]. Sophisticated attacks on IoT smart homes are not easily detected by traditional firewalls and intrusion detection systems. Machine learning, deep learning, and ensemble methods have recently been developed to boost detection accuracy and decrease the number of false positives, respectively. Combining these techniques in this study, CNN outperforms them on several datasets, obtaining an accuracy of around 99%, and the hybrid ensemble 99.8% [11]. Existing studies on intrusion detection for smart home systems with IoT typically use simulated data sets or small data sets, and do not consider the IoT devices themselves as an attack vector. This study proposes harmony search optimization of an Extra

Trees classifier for the detection of real-time traffic from 105 devices.

The proposed IDS obtained an accuracy of 99.87% in binary classification [12]. The emerging trend of smart home security systems based on the Internet of Things (IoT) demands efficient facial recognition models for resource-constrained devices. In the era of Internet of Things (IoT) enabled smart home security, efficient facial recognition models are required for resource-constrained devices. This study uses a network architecture named EfficientNet-B4 along with transfer learning and fine-tuning to enhance recognition with a small dataset. The model successfully reached an accuracy of 97% on collected images, whereas the EfficientNet-B4 model had a top-1 and top-5 accuracy of 82.9% and 96.4% [13]. Smart home devices of the IoT generation are becoming more susceptible to DDoS attacks, and it is essential to detect and mitigate such attacks in real time. This study suggests an SDN-based architecture that integrates the machine learning scheme for traffic classification on the IoT devices with the SNORT traffic analysis scheme for controller protection. SVM, Logistic Regression, Decision Tree and KNN were tested and among them Decision Tree has the maximum accuracy of 99% [14]. With IoT and machine learning, home security becomes intelligent, with the ability to detect threats in real time based on the information from cameras and movement sensors. Three models, namely Decision Tree, transfer learning, Logistic Regression, and SVM are evaluated in this study. The system proposed in this work was successful in reaching an accuracy of 99.2%, while Decision Tree and transfer learning performed better than SVM and Logistic Regression [15]. Anomaly detection is crucial in human activity for smart homes, especially when residents are elderly, and they may not be monitored constantly. The environment of multi-resident facilities adds to the complexities, and comprehensive anomaly datasets are limited. In this study, eight machine learning and two deep learning classifiers are compared, and it is concluded that GRU is the best when it comes to distinguishing abnormal and normal activities [16]. Smart home technologies have improved the convenience of the home, but opened up a great deal of security concerns, which are to be tackled by a good intruder detection system. The signature-based, anomaly-based, and hybrid IDS methods are the existing ones. Their interoperability with machine learning, IoT, and edge and cloud computing will be explored with a focus on dynamic, privacy-sensitive security solutions [17].

Research Gap: An overview of these studies reveals that most of the current studies are dedicated to the selection of an effective classifier and to the assessment of its detection performance, whereas relatively little work has been done on reducing the number of features without loss of useful information. The studies also process the information of features in various ways. In [10, 14, and 15] the different classification algorithms are explored mainly, while, in [11] the deep learning and ensemble methods are combined, and in [12] an optimization technique is applied in conjunction with an Extra Trees classifier. All of these studies look at the potential of various learning methods, but none of them explore feature redundancy and feature relevance in combination in a single feature-selection method. If removal of highly correlated features is undertaken alone, then it does not indicate which features, if any, from the remaining features have the most influence on target class prediction. This gap inspires the proposed CAHFS approach, which combines these two aspects: correlation analysis is applied to solve the redundancy problem, and Mutual Information and Random Forest feature importance are used to find informative features.

To overcome these problems, this study proposes a hybrid feature-selection method entitled CAHFS, which is based on the combination of correlation analysis, Mutual Information, and the feature importance of Random Forest. The goal is to eliminate features that are not needed while preserving features of the smart-home network traffic that are useful for intrusion detection. The resulting feature set is then evaluated on several machine-learning classifiers to assess the overall predictive accuracy of the classifiers and the error patterns.

III. METHODOLOGY

In this section, the methodology that has been adopted towards the development of the proposed smart home intrusion detection framework is presented. Data collection and data preprocessing are the first steps in the process, followed by exploratory data analysis to gain insights into the nature of the network traffic. The main methodological part is then a correlation-aware hybrid feature selection (CAHFS) that selects the most useful and least redundant features. Selected features are then applied to build and test various machine learning models under the same experimental conditions to compare them. As a general principle, the proposed workflow is designed to minimize the original feature space whilst preserving the information required for reliable intrusion detection and ensuring a fair comparison between the models evaluated. Fig. 3 illustrates the steps adopted.

A. Data Collection

The dataset used in this study was retrieved from a publicly available source [18] The dataset was captured under normal operation as well as from 7 different multi-stage attack scenarios that can arise in a smart home environment that hosts end devices of heterogeneous nature. The dataset was published in 14 January 2026 by Amrita Vishwa Vidyapeetham. The dataset comprised (178831 x 22).

The distribution of training and validation data for the two classes in the dataset is shown in Fig. 4. The test set contains 29,872 samples and was kept separate from the model development t process for final evaluation. Approximate Class ratio: 57348 normal samples, 91611 attack samples (1.591. The data set is moderately imbalanced as the attack samples outnumber the normal samples. To minimize the impact of this imbalance during the training of these models, SMOTE (Synthetic Minority Over-sampling Technique) was used to augment the training data. This would help to ensure that the minority class was represented and the likelihood of the models becoming biased towards the majority class was minimized.

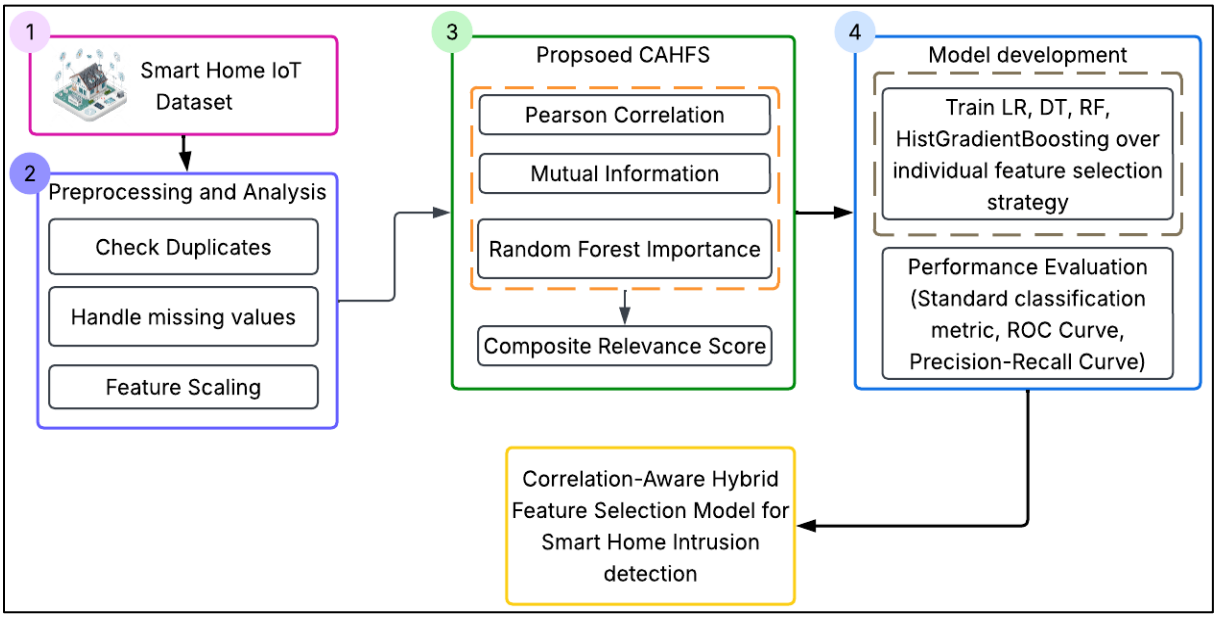

Fig. 3. Overall research pipeline.

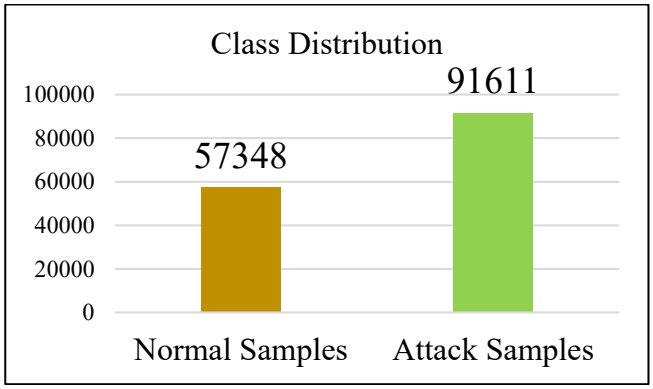

Fig. 4. Class distribution of training and validation data.

B. Preprocessing and Analysis

The raw network traffic is first cleaned and formatted to be consistent before creating the classification models. Records are duplicated and deleted as needed. All infinite values are replaced with missing values, and all values missing after that are processed in a preprocessing procedure that is tailored only to the training data. The training portion is then split into separate training and validation data sets with stratified sampling. This means that the number of normal instances is the same in both sets as the number of attack instances [19][20].

C. Proposed Correlation-Aware Hybrid Feature Selection (CAHFS)

In the context of smart home intrusion detection, feature selection plays a crucial role as network traffic datasets can frequently be large and include numerous flow and statistical features, some of which may lack discriminatory power or be redundant. This work presents a novel approach named Correlation-Aware Hybrid Feature Selection (CAHFS) to minimize the above redundancy and enhance the learning efficiency. CAHFS rates features based on three criteria: relevance to the intrusion class, importance in predicting the class, and redundancy with the other features selected. Mutual Information (MI) is a measure of target relevance, and Random Forest (RF) importance is a measure of predictive contribution. Pearson correlation is then applied to determine whether there is information that is shared between features. These criteria are aggregated into a score, with informative features getting a higher score and highly redundant features getting a lower score, with the criteria being correlation-aware. The procedure consists of four steps: 1) correlation analysis, 2) MI-based relevance estimation, 3) RF-based importance estimation, and 4) correlation-aware score fusion. This ranking is then applied to determine a small number of useful features to be used for the intrusion detection models.

Let the traffic in the dataset $\mathcal{D}$ be denoted by X and the available features be represented as d the corresponding intrusion classes be shown as Y_i Hence, the original feature space and training dataset is given by Eq. (1) and (2), respectively:

$$\mathcal{F} = \{X_1, X_2, \dots \dots X_d\} \tag{1}$$

$$\mathcal{D}_{t_r} = \{(X_i, Y_i)\}_{i=1}{}^{N} \tag{2}$$

1) Pearson correlation analysis: In this stage, the proposed CAHFS method examines the relationship between every pair of traffic features using Pearson correlation [21]. The correlation between features X_i and X_k is calculated by:

$$r_{jk} = \frac{\sum_{i=1}^{N}(X_{ij}-\overline{X_i})(X_{ik}-\overline{X_k})}{\sqrt{\sum_{i=1}^{N}(X_{ij}-\overline{X_i})^2}\sum_{i=1}^{N}(X_{ik}-\overline{X_k})^2} \tag{3}$$

A feature pair is highly correlated when $|r_{jk}| \geq 0.90$, thus the highly correlated feature set is defined as:

$$\mathcal{C} = \{(i,k): |r_{jk}| \geq 0.90\} \tag{4}$$

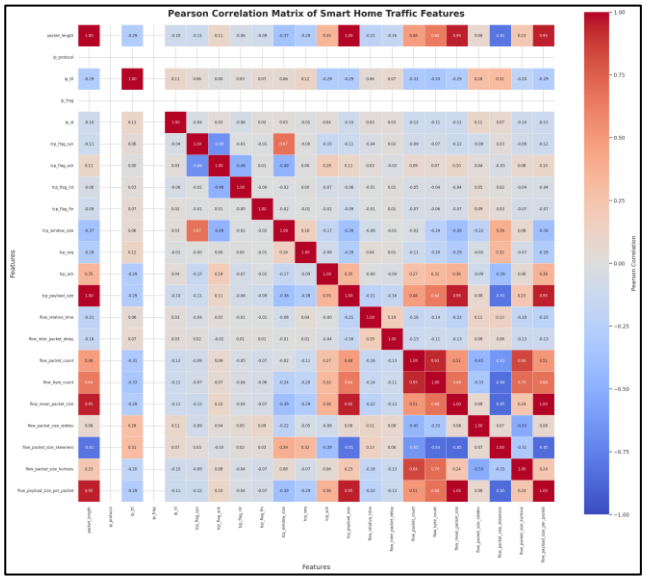

Fig. 5. Selected features using Pearson correlation method.

The training data was used to calculate the Pearson correlation matrix as illustrated in Fig. 5. It gives an idea of the linear relationships between the traffic features themselves. Correlation values near +1 or −1 signify a strong correlation, and values near 0 signify that there is little or no linear correlation. For this analysis, feature pairs having an absolute correlation coefficient value higher than 0.90 were considered highly correlated and redundancy was noted during feature selection.

This step identifies the potential redundancy among smart home traffic features.

2) Mutual Information (MI): After identifying the correlated features, mutual information is calculated to determine how strongly each feature is associated with intrusion class [22]. For feature X_j and Y represents the intrusion class, the MI score is calculated as:

$$\mathrm{I}_j = \mathrm{I}(X_j; Y) \tag{5}$$

A larger I_j indicates that the features provides more information about the intrusion class. The normalization of the MI score is defined as:

$$\overline{\mathrm{I}_j} = \frac{\mathrm{I}_j - \mathrm{I}_{min}}{\mathrm{I}_{max} - \mathrm{I}_{min}} \tag{6}$$

The scores of the input features are shown in terms of the Mutual Information with the intrusion class in Fig. 6. The higher the MI, the more information a feature contains about the class it represents and therefore the more value it is for discriminating between normal and attack traffic. Unlike Pearson correlation, which is primarily used in detecting linear relationships, Mutual Information can also detect nonlinear dependencies. This can be helpful in recognizing informative features that might not have been captured by the correlation analysis.

This step is important because MI can capture nonlinear relationships that may not be captured through the Pearson correlation method.

3) Random forest feature importance: A balanced Random Forest classifier is trained using the training dataset. The predictive contribution of each feature is obtained from the trained ensemble [22][23]. For feature X_j, its random forest importance is defined by:

$$\mathcal{F}_j = RFimportance(X_j) \tag{7}$$

The normalization score of $\mathcal{F}_j$ is expressed by:

$$\overline{\mathcal{F}_j} = \frac{\mathcal{F}_j - \mathcal{F}_{min}}{\mathcal{F}_{max} - \mathcal{F}_{min}} \tag{8}$$

A larger $\mathcal{F}_j$ indicates that feature contributes more strongly to the predictive decisions for Random Forest.

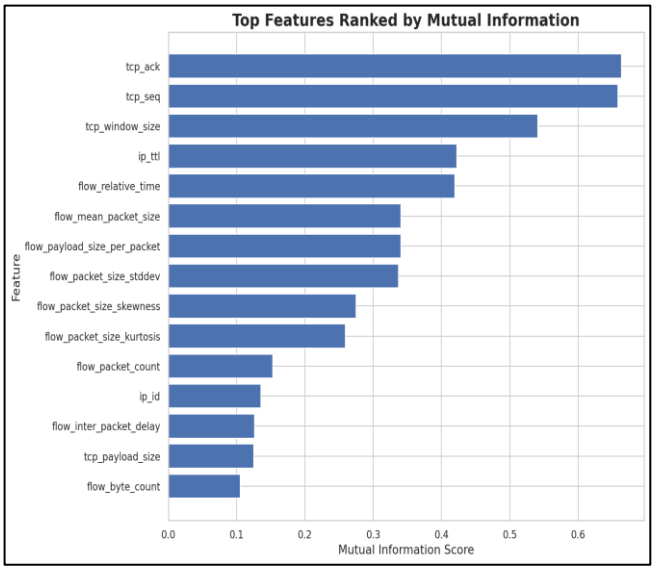

Fig. 6. Top features ranked by MI method.

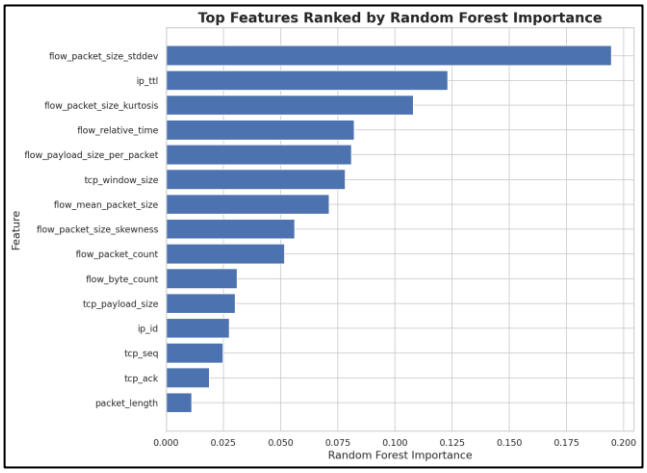

Fig. 7. Random forest importance features.

The importance scores obtained by the Random Forest model using the training data is shown in Fig. 7. The larger the importance score, the more the feature influences the prediction of the model; the smaller the score, the less the feature influences the model. This ranking is another perspective on feature usefulness in addition to Mutual Information and correlation

analysis, since Random Forest can discover nonlinear patterns in the data

4) Proposed CAHFS-based composite score: For feature $\mathcal{S}$ represent the set of features that have already been selected. For a candidate feature X_j its correlation redundancy with the selected features is defined as:

$$\mathcal{R}_j = \max_k \in \mathcal{S}[r_{jk}] \quad (9)$$

Finally, the normalized MI and RF scores are then combined using equal weights to obtain the final composite score for each feature:

$$\mathcal{S}_j^{CAHFS} = \frac{1}{2}\bar{\mathrm{I}}_j + \frac{1}{2}\bar{\mathcal{F}}_j \quad (10)$$

where, $\bar{\mathrm{I}}_j$ represents the normalized MI score, while $\bar{\mathcal{F}}_j$ denotes the normalized Random Forest Importance score. $\mathcal{S}_j^{CAHFS}$ shows the final CAHFS composite score of features X_j.

This means that a feature is preferred when it is informative about the intrusion class, useful for prediction, and not excessively redundant with features that have already been selected.

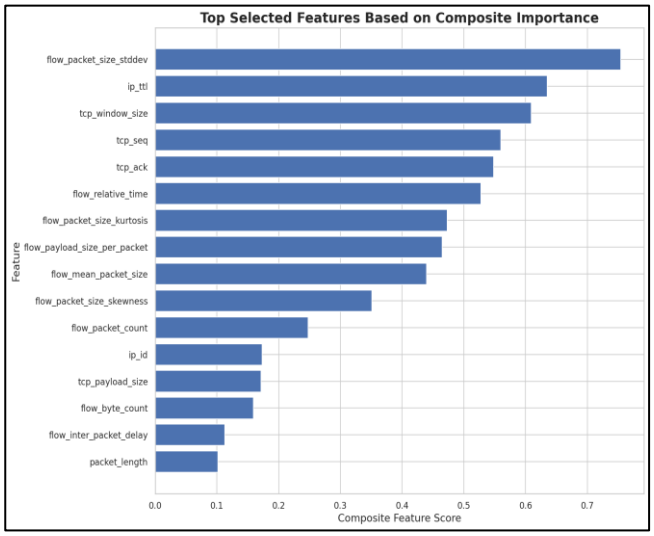

Fig. 8. Composite importance of selected features.

The final feature ranking derived by CAHFS (after merging the relevance scores obtained from Mutual Information with feature importance scores from Random Forest) is presented in Fig. 8. The higher the combined scores for each feature, the closer it will be at the top of the ranking, and the closer it is to the top, the more likely it is to be selected according to the predetermined retention criteria. The reduced feature set is then fed into all the classification models, and the experimental conditions are kept the same during the evaluation.

The final number of features was rounded to the nearest whole number and 16 features remained out of an initial set of 22 features. For consistency, the same retention threshold was used in all the feature-selection experiments. In this study, there is no systematic testing of different retention levels, and this is identified as a limitation and is suggested for further work to test the effects that various sizes of feature sets have on the classification performance-dimensionality tradeoff.

Algorithm-1: Proposed CAHFS Method

Input: training feature matrix $\boldsymbol{X} \in \mathbb{R}^{N \times d}$, training labels $\boldsymbol{Y} \in \{0,1\}^N$, correlation threshold $\tau = 0.90$, Feature retention ratio $r = 0.70$

Output: selected Feature Subset $\mathcal{S}$

Start:

1. Load $X \in \mathbb{R}^{N \times d}$ and $\in \{0,1\}^N$
2. Compute Pearson correlation Matrix $\mathcal{R}_j$ using Eq. (3)
3. Identify highly correlated feature pairs using Eq. (4)
4. Compute Mutual Information between each feature and target labels using Eq. (5)
5. Train a Random Forest classifier using X and Y
6. Extract Feature Importance using Eq. (7)
7. Normalize the MI and RF scores using Min-Max normalization
8. Calculate the final composite CAHFS score using equal weights 0.50 for MI and RF, as defined in Eq. (10)
9. Rank all features in descending order according to their CAHFS score.
10. Determine the number of retained features using the predefined retention ratio:
11. $N_{SELECTED} = \lceil rN_{features} \rceil$
12. Select Top-ranked features
13. Return $\mathcal{S}$

End

The proposed Correlation-Aware Hybrid Feature Selection (CAHFS) procedure is described in Algorithm 1. It first calculates the Pearson correlation matrix for the training data and finds the pairs of features that are highly linearly correlated. The relevance and importance of each feature with respect to intrusion detection is then measured separately using Mutual Information and Random Forest. The scores from both measures have been normalized; the scores of the two measures are then pooled together with equal weights to get the overall relevance score. This combined score is used to rank the features and the top 70% are selected as the final set of features. These selected features are then given to the machine-learning models, which would then be trained and evaluated in turn.

D. Model Development

Four machine-learning models are used to evaluate the selected 16 features. The models are linear classification, single tree learning, bagging, and gradient boosting.

1) Logistic regression: As a linear baseline to investigate whether the selected features can distinguish between normal and attack traffic with a simple decision boundary [24].

2) Decision tree: Recursively partitions the feature space based on decision rules, thus enabling the model to learn nonlinear attack patterns [25].

3) Random forest: Aggregates several decision trees to achieve greater stability and to pick up more interactions among the features [26].

4) HistGradientBoosting: An efficient model, based on the gradient boosting framework, to learn non-linear relationships

using the histogram technique and to yield an excellent model with the selected feature set [27].

TABLE I. HYPERPARAMETERSARAMETERS

Models	Parameters	Description
LR	C	0.1
	Penalty	L2
RF	n_estimators	100
	Max_depth	None
	Min_samples_split	2
	Min_samples_leaf	1
DT	Max_depth	10
	Min_samples_split	2
	Min_samples_leaf	1
	Entropy	
HistGradientBoosting	Learning Rate	0.1
	Max_iteration	150
	Max_leaf_nodes	31
	12_regularization	0.1

The parameter values used for the four machine-learning classifiers in the experiments are shown in Table I. These settings were kept constant for all feature-selection tests, enabling the comparison of the different models under the same conditions. The validation set was used during the development of the model for evaluation and tuning, and the test set was not used until the final evaluation. These details have been added to the revised manuscript to adequately describe the experimental setup and to aid in the reproduction of the study. Logistic Regression: L2 regularization (C=0.1). Random Forest employed 100 trees and did not specify the maximum depth of the trees. The maximum depth was 10 for the Decision Tree, and entropy was chosen as the splitting criterion. The model, named HistGradientBoosting, was trained with a learning rate of 0.1, 150 boosting iterations, 31 maximum leaf nodes, and L2 regularization of 0.1. The same settings were used in all experiments to ensure as far as possible, a consistent comparison among the various feature subsets.

IV. RESULTS AND DISCUSSION

Experiments were all performed in Python, and all the usual machine-learning libraries were used for data pre-processing, feature selection, model development, and evaluation of results [28]. The data set was split into training, validation, and test sets to maintain consistency and an unbiased experimental procedure. All the parameters of the preprocessing were set by the training data alone, and SMOTE was used to solve the class imbalance problem in the training set. Feature selection was also performed based on the training data only. Models were developed using the training set, and the validation set was used to select and tune the model parameters. The test set was held entirely apart from the entire development process and used only for the final evaluation. The data used was made up of 119,167 training samples, 29,792 validation samples, and 29,872 test samples as seen in Table II. By not changing the test set during model development, the final results were able to give a more accurate indication of the degree of generalization of the models evaluated.

TABLE II. DISTRIBUTION OF SAMPLES

Dataset Partition	Samples	Percentage
Training	(119167, 16)	66.64%
Validation	(29792, 16)	16.70%
Testing	(29872,16)	16.66%

TABLE III. PERFORMANCE OF ML CLASSIFIERS USING PROPOSED CAHFS

ML models	Accuracy	Precision	Recall	F1 score
LR	62.71%	56.69%	51.80%	54.14%
RF	80.04%	82.29%	66.76%	74.97%
DT	85.61%	84.70%	80.69%	82.65%
HistGradientBoosting	91.03%	92.78%	85.55%	89.02%

Table III represents the performance of ML classifiers using the proposed CAHFS. Amomng classifiers HistGradientBoosting classifer outperforms acorss all metric as compared to other models by achiving an of accuracy (91.03%), precision (92.78%), recall (85.55%), and f1 score (89.02) its superiro performance can be attributed to its nonline fetaure inetractions and complex decision boundries, which are improtant for distinuguishing normal and attack traffic. Followed by DT, which exhibits accuracy (85.61%), precision (84.70%), recall (80.69%), and F1 score (82.65%). The RF classifier performs average, obtaining an accuracy (80.04%), precision (82.29%), recall (66.76%), and F1 score (74.97%). The LR classifer perfomed poor by achieving the lowest accuracy (62.71%), precision (56.69%), recall (51.80%), and F1 score (54.14%), likely because its linear decision boundary is less effective for the complex relationship present in the selected features.

TABLE IV. CLASS-WISE ERROR CHARACTERISTICS AND SPECIFICITY OF THE EVALUATED ML CLASSIFIER ON UNSEEN TEST SET

Model	True Negative	False Negative	True Positive	False Positive	Specificity	Overall error rate
LR	12160	6116	6574	5022	0.707	0.372
DT	15333	2451	10239	1849	0.892	0.143
RF	15437	4218	8472	1745	0.898	0.199
HistGradientBoosting	16337	1834	10856	845	0.950	0.089

Table IV summarizes the errors of the evaluated classifiers on the test set that had not been included in the development of the classifiers. HistGradientBoosting had the best performance of all four models. It had the lowest false-positive rate (4.92%)

and the lowest false-negative rate (14.45%), the highest specificity (95.08%), and the lowest overall error rate (8.97%). This in turn allowed the model to successfully prevent false alarms and missed attacks on normal traffic**.** DT gave the next best results of a 19.31% false-negative rate, 10.76% false-positive rate, and 14.39% error rate. The error rate for Random Forest was higher (19.96%) due to a higher false-negative rate of 33.24%, even though it had a slightly lower false-positive rate (10.16%). Logistic Regression did the worst with false-positive and false-negative rates of 29.23% and 48.20%, respectively. In general, the results obtained indicate that HistGradientBoosting gave the best error profile, especially with the number of false alarms and the number of missed intrusion cases.

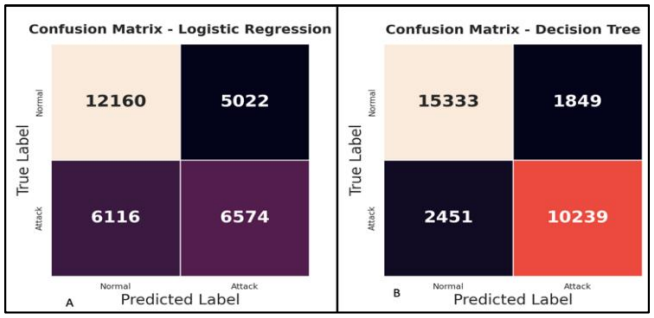

Fig. 9. Confusion matrix for LR and DT.

Fig. 9 illustrates the performance of LR and DT models over unseen test samples. In Fig. 9 (A), the confusion matrix for LR is shown, where the model exhibits lower performance, correctly classifying (18734) samples out of (29872), while (11138) samples were misclassified. Conversely, in Fig. 9(B), the performance of the DT classifier is shown. From the total samples (29872), 25572 samples were correctly predicted; only 4300 samples were misclassified.

Fig. 10 represents the performance of RF and HistGradientBoosting classifiers over test samples. In Fig. 10(A) the performance of RF model is depicted where the model correctly classifed (23909) samples from total (29872) while 5963 samples were wrongly classified. On the other hand, Fig. 10(B) shows the confusion matrix of the HistGradientBoosting classifier, where the classifier remarkably classified (27193) samples with only 2679 misclassifications.

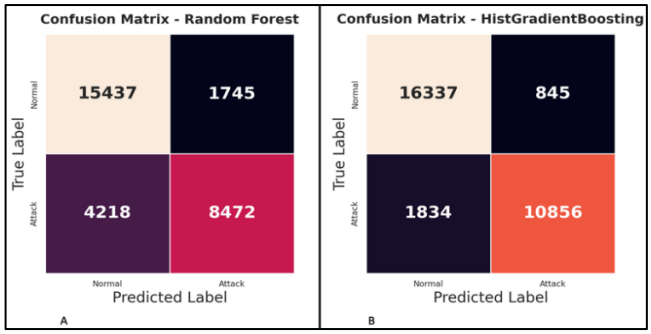

Fig. 10. Confusion matrix for RF and HistGradientBoosting.

The ROC curves for the four ML classifiers using the sets of features selected by the proposed CAHFS method are presented in Fig. 11. HistGradientBoosting (0.964) performed best with a ROC-AUC value, followed by RF (0.910) and DT (0.848). LR had the lowest ROC-AUC of 0.669, which clearly displayed its separation capability between two classes. The results show that HistGradientBoosting performed better than the other models for distinguishing between the desired classes for a variety of classification thresholds. It may be because its higher ROC-AUC allows it to learn the nonlinear relationship and interaction among the selected features. The trees are constructed on a sequential basis, with each new tree correcting the errors made by previous trees, which can enhance the overall classification performance. The opposite of this is true for the lower ROC-AUC value achieved by LR, which indicates that there is not a good linear association between the features used and the class labels.

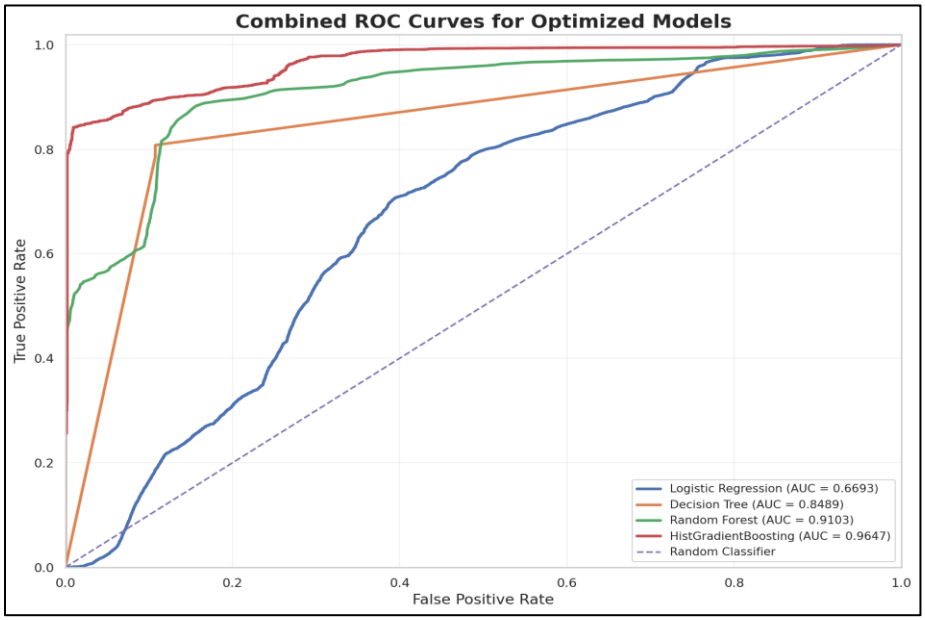

Fig. 11. ROC Curve of ML classifier using proposed CAHFS.

TABLE V. COMPARATIVE EVALUATION OF ML CLASSIFIERS USING ALTERNATIVE AND PROPOSED FEATURE-SELECTED STRATEGIES

Feature Methods	No Features	Models	Accuracy	Precision	Recall	F1 score	ROC-AUC
All	22	LR	63%	60%	61%	60%	0.673
		DT	86%	84%	83%	83%	0.855
		RF	80%	82%	67%	74%	0.916
		HistGrdaientBoosting	89%	90%	85%	87%	0.955
Pearson	18	LR	63%	59%	49%	53%	0.647
		DT	86%	86%	82%	84%	0.863

		RF	85%	84%	80%	81%	0.91
		HistGrdaientBoosting	91%	91%	90%	90%	0.96

The performance of the four machine-learning classifiers in the three feature selection approaches (conventional feature selection, the proposed CAHFS approach, and the full set of features) is compared in Table V. Overall, the best results are obtained with HistGradientBoosting for varying feature configurations. It was able to reach an accuracy of 89%, an F1-score of 87%, and a ROC-AUC of 0.955 when using all 22 features. After feature selection using Pearson, accuracy and F1 score were 92% and 90%, respectively, while the number of selected variables decreased to 18. Further, the number of features was reduced to 16 variables by Mutual Information or RF selection, which yielded similar high ROC-AUC values of 0.964 and 0.963, respectively, in HistGradientBoosting. The proposed CAHFS method also generated competitive outcomes using just 16 features. With the HistGradientBoosting model, it achieved 91% accuracy, 90% recall, 90% F1 score, and a ROC-AUC of 0.960. The results indicate that the CAHFS can eliminate less useful variables without compromising the important information for classification. That is, the feature set is reduced, but information is still retained and input representation is compact. The superior results of HistGradientBoosting over LR, DT, and RF suggest that there are possible nonlinear relationships or interactions between the features in the data. A gradient-boosting approach is better suited than a linear classifier or traditional tree-based models to detect such patterns.

CAHFS provides slightly less accurate and precise classification, but with two fewer features. This indicates that the main advantage of CAHFS lies in its ability to provide a more compact and efficient feature representation rather than in achieving the highest accuracy. The overall results indicate that the reduction of input features while preserving the information required for reliable classification is possible with CAHFS.

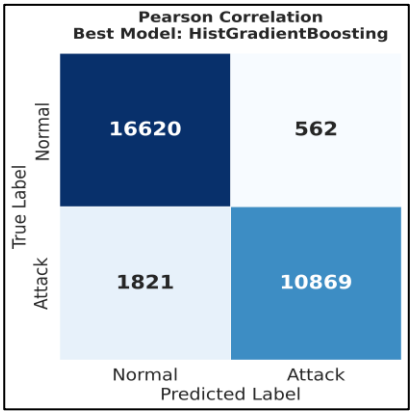

Fig. 12. Confusion matrix for the best-performing model.

The confusion matrix for the best-performing experimental setup (Pearson Selected-HistGradientBoosting) is presented in Fig. 12. The matrix shows that the model was able to correctly predict the majority of the normal and attack samples, with a relatively small number of false predictions. This is in line with the very good accuracy and F1-score of the model. The results also indicate that some redundant information was removed by using the features selected by the Pearson method without the loss of the features important for distinguishing between the two classes. This led to HistGradientBoosting having a good classification result on fewer input variables.

The ROC curve of the Pearson-selected HistGradientBoosting configuration is presented in Fig. 13. The curve remains in the upper left part of the plot, suggesting that the model has the ability to distinguish between normal and attack samples for various decision thresholds. The corresponding ROC-AUC value is also a sign of its overall discriminatory power. The ROC-AUC scores are higher for classifiers that can achieve a good balance between true positives and false positives for a range of thresholds. This indicates that the feature set chosen has the information necessary for the effective detection of intrusions.

The precision-recall curve of the Pearson Selected-HistGradientBoosting is shown in Fig. 14. The curve depicts the changes in precision and recall with varying classification thresholds. The analysis is particularly relevant in this context to investigate the ability of the model to find attack samples and keep the rate of incorrect positive predictions under control. The accuracy of the classifier's performance in the precision-recall graph shows that it can identify a significant percentage of attack samples with only a modest number of false alarms. In addition to the ROC analysis, this gives a better sense of the model's positive class identification ability.

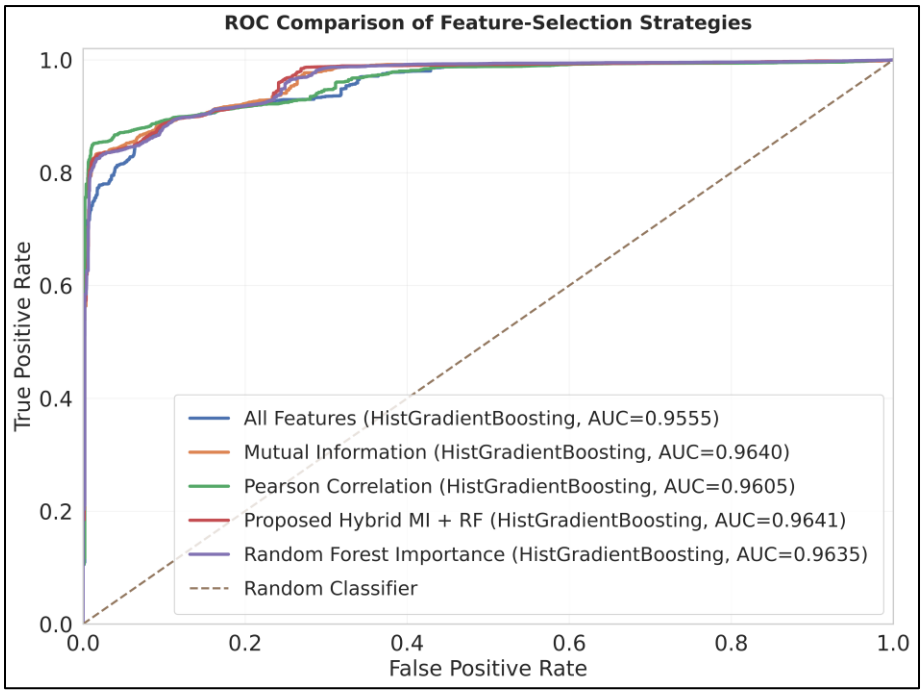

Fig. 13. ROC curve analysis of the best-performing model.

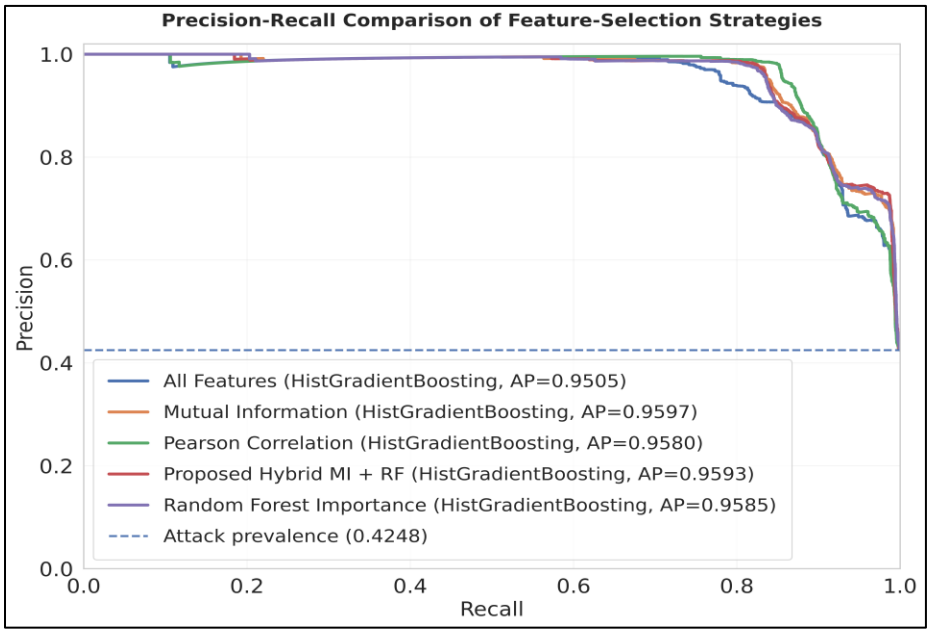

Fig. 14. Precision-recall curve of the best-performing model.

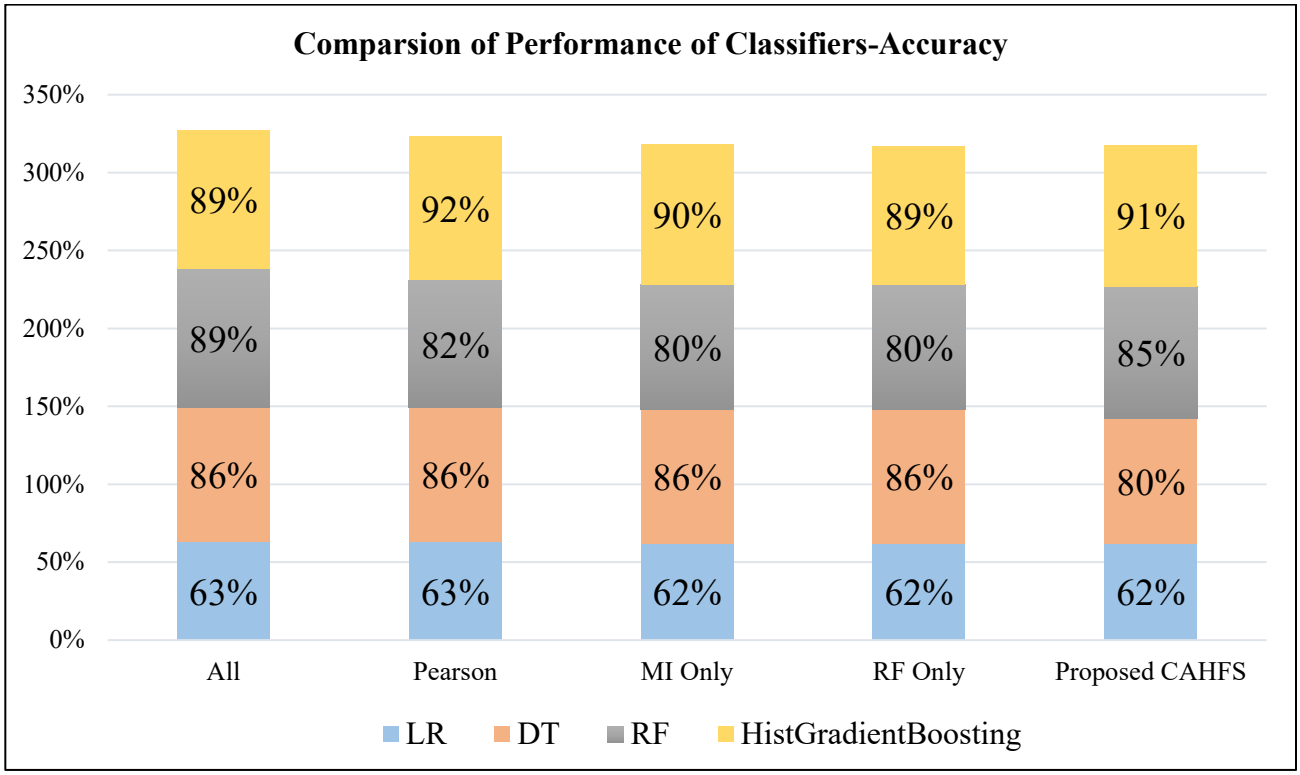

Fig. 15. Comparison of model performance across accuracy.

The results of the machine-learning models evaluated are compared in Fig. 15 under the various feature-selection strategies. Results indicate that the effect of feature selection was different for the classifiers. The Logistic Regression model performed relatively poorly over the tested feature sets while HistGradientBoosting performed the best. It is also observed from the comparison that a decrease in the number of features did not necessarily mean that the classification results are worse. In a few instances, the elimination of less informative or redundant variables resulted in better model performance. The proposed CAHFS method also yielded competitive results, with only 16 features, demonstrating that the selection of a set of features can provide a compact representation without loss of information relevant to intrusion detection.

V. Discussion

The experimental results demonstrate that the proposed correlation-aware hybrid feature selection (CAHFS) framework is able to reduce the input feature number without significant degradation in ID performance. Overall, HistGradientBoosting performed best when compared to the other classifiers, with an accuracy, precision, recall and F1-score of 91%, 91%, 90%, and 90%, respectively, as reported in Table III. The values indicate that the model could successfully detect the attacks and had a low rate of false alarms. Logistic Regression, however, did not do as well – indicating that the patterns in the logistic regression model between the features of the network traffic and the attack classes are not well described using only a linear decision boundary.

The difference is also evident in the results of the tests reported in Table IV. HistGradientBoosting had the best overall error rate of 8.9% and the highest specificity of 95.0%. It also made fewer misclassifications than the other classifiers. This is crucial for a smart home intrusion detection system, as false alarms can make a security system hard to manage, and missed attacks can let harmful activity slip through the cracks. These results are confirmed by the confusion matrices displayed in Fig. 9 and 10, which illustrate the accuracy of the models at predicting the test samples for the two types of classification outlined above.

Regarding RQ1, the results indicate that CAHFS was able to classify the same number of features as the original with a modest drop in classification accuracy. The accuracy was slightly higher with Pearson-based selection, but CAHFS still obtained a ROC-AUC of 0.96 using fewer features. This indicates that the proposed hybrid technique was able to remove less useful information and retain the features that are important for distinguishing between normal and attack traffic.

This can be observed in the ROC analysis shown in Fig. 11. For the ROC-AUC scores, HistGradientBoosting was able to distinguish normal from attack traffic for most classification thresholds, with an AUC score of approximately 0.96. A possible explanation for this better performance is that it can derive non-linear relationships between features. The interactions among multiple variables may be present in the network traffic produced by a smart-home environment, and may not be well captured by a linear model.

From results presented in Table V, the selection of the feature-selection method also had a significant impact on the results of the classification. The best accuracy, 92%, was obtained by the Pearson-based selection. Despite this, the

original 22-feature representation was reduced to just 16 features, yielding competitive results of 91% accuracy, 90% recall, 90% F1 score, and a ROC-AUC of 0.96. Fig. 12- 15 show the individual results of the model performance, including, among others, the confusion matrix, the ROC behavior, the precision-recall relationship, and a comparison of the various feature-selection strategies.

For RQ2, the overall best performance was achieved by the HistGradientBoosting classifier. This ROC-AUC, specificity (around 95%), and overall error rate (around 8.9%) suggest that it performed better at separating the attack traffic from the normal traffic and with a relatively low rate of misclassifications. The results indicate that HistGradientBoosting performed better for the feature representation in this study than LR, DT, and RF.

It should be noted that the results shown in Tables III-V were conducted with a single training, validation, and testing split. It is important to note that the relatively small differences between the feature-selection methods, particularly between the one-two percentage-point differences in accuracy, should not be interpreted as a statistically significant advantage. Repeated experiments or cross-validation with variance estimations would be necessary to draw such conclusions. All feature-selection methods and classifiers were, however, tested on the same split to provide a basis for comparison. Therefore, the single split used in this study is recognized as a limitation in this study. Future work will consider multiple splits (or cross-validation) to get a better idea of how they perform.

1) Practical implication: This decrease in the number of features is also useful for practical use. A compact feature set can minimize the data processing and storage requirements, a benefit for smart-home gateways and other IoT devices that have restricted computing power. Meanwhile, the increased specificity achieved by the more powerful models could help to reduce false positive alerts for security. The overall detection performance also indicates that the proposed method may be beneficial for the real-time monitoring of network traffic in smart-home scenarios; however, a further evaluation is necessary in realistic deployment scenarios.

2) Limitations: Some restrictions remain to be noted. The experiments were done with one dataset, so the results might not reflect the performance of CAHFS in other smart home scenarios or attacks. We further evaluated the feature-selection method using a pre-defined set of hand-crafted machine-learning classifiers in one experimental configuration. Other investigations may be carried out to assess the method with various datasets, to compare the method with a broader set of feature selection methods, and to look into adaptive as well as deep learning-based intrusion detection approaches.

VI. Conclusion

This study proposed a novel hybrid feature selection (HFs) scheme, termed as Correlation-Aware Hybrid Feature Selection (CAHFS), for machine learning-based intrusion detection (IDS) in smart-home IoT networks. The primary objective was to minimize the number of features that the classifiers use while retaining as much information as possible for differentiating between normal and attack traffic. To analyze the impact of feature selection on the classifiers, four machine learning classifiers were tested with various feature sets. Overall, the best-performing model was HistGradientBoosting. It had 16 features in the CAHFS feature set and its accuracy, precision, recall, F1-score, and ROC-AUC were 91%, 91%, 90%, 90%, and 0.96, respectively. The model also achieved around 95% specificity and an overall error rate of 8.9%. These results were supported by the confusion matrix and ROC results, which also demonstrated that the model was able to correctly classify normal and attack traffic with relatively few misclassifications. One of the most important results of this work is that the CAHFS managed to map 22 to 16 variables and maintain a competitive level of classification results. The fewer features used, the less data will be processed by the detection system, and therefore, fewer resources will be consumed by the detection system, which may be beneficial in smart-home environments where computing and storage resources are limited. Overall, the results indicate that the use of correlation along with the feature importance from the Mutual Information and the Random Forest may be able to reduce the number of selected features without affecting the detection performance significantly. These results come from one dataset with one experimental setup, however, they should be interpreted accordingly and not as generalizable to other datasets and/or deployments. Future research should investigate the approach on other datasets and under a variety of experimental conditions; ideally with replication to better assess generalizability.

VII. Future Work

These signs are promising, but there are a number of issues that could be explored further. The first is validation on additional datasets and independent test environments. Testing of CAHFS on various smart-home networks, attack scenarios, and device configurations would give a better understanding of the effectiveness of the method in expanding the dataset included in this study. Another direction which is useful is adaptive feature selection. Network traffic varies according to the change of applicable devices, applications, and communications. A feature selection technique that is adaptive to the changing nature of traffic could make the system more appropriate for long-term operation. Further research is also needed for comparing CAHFS with a wider variety of models such as ensemble methods, lightweight neural networks, or deep-learning models. In addition to classification performance, processing time, memory consumption, and computing cost would be beneficial to consider to see if the framework can be effectively deployed on smart-home gateways and edge devices.

AI-Based Preprocessing and R-Squared Weighted Federated Aggregation for Robust Healthcare Signal Imputation

Benachir Rigalma, Hamid Ouhnni, Meryam Belhiah, Soumia Ziti
IPSS Team, Faculty of Sciences, Mohammed V University in Rabat, Morocco

***Abstract*—Federated learning is an emerging paradigm for collaborative model training in healthcare applications where sensitive patient data cannot be centralized due to privacy concerns; however, missing values in physiological signals remain a major challenge, often leading to degraded model accuracy and unstable convergence. To address this issue, this work presents an AI-based preprocessing framework that combines advanced imputation methods, including K-Nearest Neighbors (KNN), Autoencoder reconstruction, and Generative Adversarial Networks (GAN), with classical baselines such as mean and median imputation. Building on this preprocessing stage, this study proposes a novel R-squared weighted aggregation strategy that dynamically scales clients' contributions based on their prediction quality. The experiments were conducted on BIDMC physiological datasets with missingness rates ranging from 0.1 to 0.5 across multiple federated clients. Results show that weighted aggregation converges to lower RMSE and MAE than classical FedAvg, especially in the early rounds where high client heterogeneity exists. The proposed method adapts to client quality, thereby providing robust convergence and stability, resulting in balanced performance. These results demonstrate that combining AI-based preprocessing with R-squared weighted aggregation effectively improves the reliability of federated learning in healthcare IoT systems. The proposed approach presents a scalable and feasible solution for real-world scenarios where data incompleteness and client heterogeneity are inevitable.**

***Keywords*—Missing data imputation; healthcare signals; weighted aggregation; AI-based preprocessing; federated learning**

I. Introduction

Federated learning has emerged as a significant paradigm in contemporary artificial intelligence, particularly in sensitive fields such as healthcare, finance, and education [1]. Its main advantage is that models can be trained collaboratively across multiple institutions without requiring direct access to raw data, thereby preserving privacy and security [2]. This distributed approach allows knowledge sharing while respecting data governance rules, which is especially critical in the medical domain where patient confidentiality is paramount [3]. Federated learning supports distributed training and provides an opportunity to exploit heterogeneous datasets while addressing ethical and legal concerns [4]. Despite its promise, federated learning faces persistent challenges related to heterogeneity and incompleteness of client data [5]. In practice, datasets often contain missing values, imbalanced distributions, and varying quality levels [6]. Classical aggregation methods such as FedAvg treat all clients' updates equally, which can lead to unstable convergence and reduced accuracy when some clients provide noisy or unreliable updates [7]. This gap between theoretical promise and practical reliability underscores the need for adaptive strategies that account for differences in client data quality [8].

The central research question driving this work is: How can federated learning be improved to guarantee reliable performance in the presence of heterogeneous and incomplete client data, particularly in healthcare applications where accuracy and stability are paramount?

A. Novelty and Contributions

This study proposes a new federated learning framework in two aspects. First, it combines a variety of AI-based imputation strategies (K-Nearest Neighbors, Autoencoder reconstruction, and Generative Adversarial Networks) with classical baselines (mean and median) to handle missing data in healthcare signals. Second, it proposes an R-squared weighted aggregation mechanism that dynamically weights the clients' contributions based on the quality of their predictions to reduce the effect of client heterogeneity. The scientific contributions of this work can be summarized as follows: Firstly, it systematically integrates advanced imputation strategies with a client-quality-aware aggregation scheme in federated learning; Secondly, it provides the formal derivation of both classical FedAvg and the proposed R-squared weighted aggregation, emphasizing the differences and benefits of the proposed approach; Thirdly, it carries out extensive experiments on BIDMC physiological datasets with different missingness rates, including direct comparisons among imputation methods and statistical validation of aggregation performance. Finally, it shows practical impact by improving reliability and stability in federated healthcare IoT systems, providing a scalable approach for real-world scenarios where data incompleteness and client diversity are unavoidable. This study proposes a framework to solve this problem that combines several AI-based preprocessing techniques with a new R-squared weighted aggregation mechanism. The main contributions are three. This study proposes classical baselines (mean, median) and extends them with state-of-the-art imputation methods (KNN, Autoencoder, GAN) for better preprocessing of incomplete healthcare signals. This study proposes an R-squared weighted aggregation mechanism to dynamically scale the contribution of clients according to their prediction quality. The study provides a comprehensive experimental evaluation

on the BIDMC physiological datasets with different levels of missingness, including statistical validation and comparison of imputation methods. The rest of the study is organized as follows. Section II presents the related work on imputation techniques and federated aggregation strategies. Section III elaborates on the methodology, including dataset preparation, preprocessing approaches, and evaluation metrics. Section IV reports the comparative results between classical FedAvg and the proposed R^2-weighted aggregation. Section V discusses the strengths, limitations, and practical implications of the method. Section VI concludes the study and outlines directions for future research.

II. Related Work

A. Missing Data Imputation

Missing data in physiological signals has been addressed using a variety of preprocessing techniques. Classical statistical baselines such as mean and median imputation offer computational efficiency but fail to capture nonlinear dependencies [18]. More advanced approaches include K-Nearest Neighbors (KNN), which leverages local similarity structures to estimate missing values [19], and Autoencoder-based reconstruction, which learns latent representations to infer missing entries from underlying nonlinear patterns [20]. Generative Adversarial Networks (GANs) have also been applied to model complex physiological signal distributions and generate realistic imputations [21]. Additional preprocessing strategies include outlier detection, class imbalance correction using SMOTE, normalization, and natural language processing for unstructured medical text [10–12]. Additional preprocessing strategies for healthcare data, including KNN-based imputation, outlier detection, and SMOTE-based balancing, have also been explored in prior work [9]. These methods highlight the importance of robust preprocessing in improving downstream learning performance.

B. Federated Aggregation Methods

Federated learning has introduced several aggregation strategies beyond the classical FedAvg algorithm. Weighted FedAvg incorporates dataset size into the aggregation process, while robust statistical methods such as Median, Trimmed Mean, and Krum aim to mitigate the influence of unreliable or adversarial clients [7, 13–15]. Byzantine-resilient approaches such as GeoMed and Clipped Clustering further enhance robustness under extreme heterogeneity. Adaptive weighting schemes based on gradient norms have also been proposed to improve convergence stability in non-IID environments [16, 17].

More recent methods explicitly address client heterogeneity. FedProx introduces proximal regularization to stabilize updates from diverse clients, FedNova normalizes local training to reduce objective inconsistency, SCAFFOLD employs control variates to correct client drift, and FedAdam applies adaptive optimization at the server level. These approaches modify gradient dynamics or optimization behavior to improve global model stability under heterogeneous conditions.

C. Distinction of the Present Work

The present study differs from prior aggregation strategies by incorporating a reliability-aware weighting mechanism based on the coefficient of determination (R^2). Unlike gradient-based or dataset-size-based weighting schemes, R^2 weighting directly reflects the explanatory performance of each client model. This provides an interpretable and transparent measure of client reliability, particularly relevant in healthcare scenarios where data quality varies significantly across institutions. The proposed framework integrates advanced imputation methods with R^2-weighted aggregation to enhance robustness under heterogeneous and incomplete data conditions.

III. Method

A. Dataset

This study utilized several physiological signal records from the BIDMC dataset available on PhysioNet. These include, but are not limited to, bidmc_20_Signals.csv, bidmc_28_Signals.csv, bidmc_31_Signals.csv, bidmc_35 Signals.csv, and bidmc 43 Signals.csv. The multi-channel signals in each record are RESP, PLETH, ECG leads (II, AVR, V), and ABP for one patient. Signals were sampled at 125 Hz and lasted from 6 to 10 minutes. There are 53 patients in total in the dataset. The study used a train-validation-test split of 70%-15%-15%. Synthetic missingness was introduced at the rates 0.1, 0.3, and 0.5, both by MCAR (Missing Completely at Random) and MAR (Missing at Random) procedures to mimic real-world incompleteness. To prevent data leakage, the train–validation–test split was performed strictly at the patient level. Each BIDMC record corresponds to a unique patient, and no patient appears in more than one subset. This ensures that the model is never evaluated on physiological signals originating from a patient whose data contributed to training, thereby preserving the independence of evaluation and avoiding optimistic bias. Patient-level splitting is essential in physiological time-series tasks because intra-patient temporal patterns are highly correlated; mixing segments from the same patient across different subsets would artificially inflate performance.

B. Preprocessing Approaches

1) Mean and median imputation: These classical statistical baselines replace missing entries with the average or median of the observed values in each feature. While computationally efficient, they fail to capture nonlinear dependencies and often underestimate variance [18].

2) K-Nearest Neighbors (KNN) imputation: This method estimates missing values by identifying the k most similar samples based on Euclidean distance and averaging their corresponding feature values. KNN leverages local similarity structures, making it more adaptive than mean or median imputation [19]. KNN imputation was configured with $k = 5$ using the Euclidean distance metric. These implementation details ensure reproducibility and allow replication of the experiments.

3) Autoencoder reconstruction: A deep neural network was trained to compress and reconstruct input signals. By

learning latent representations, the autoencoder can infer missing values from underlying nonlinear patterns. This approach is particularly effective in capturing hidden correlations among physiological signals [20]. The autoencoder consisted of three encoder layers (128–64–32 units), a latent dimension of 32, a symmetric decoder, ReLU activations, the Adam optimizer (learning rate 0.001), a batch size of 64, and 100 training epochs.

4) Generative Adversarial Network (GAN) imputation: A generative adversarial framework was employed, where a generator network produces plausible imputations and a discriminator network evaluates their realism. GANs are capable of modelling complex distributions, yielding imputations that closely resemble true physiological dynamics [21]. The generator was implemented with three dense layers (128–64–32 units) using ReLU and a Sigmoid output layer, while the discriminator consisted of three dense layers (128–64–32 units) with LeakyReLU activations. The optimizer was Adam (learning rate 0.0002), with batch size 64 and 200 epochs.

All hyperparameters were kept consistent across experiments to ensure reproducibility and allow exact replication of the results.

C. Relationship Between Imputation and Federated Training

The federated learning process in this study operates on imputed data, making the relationship between imputation and model training explicit. Let x_i denote the input features of client i, where missing values have been replaced using a chosen imputation method, and let y_i denote the corresponding target variable. The local learning objective for each client is to minimize a supervised loss function $L(f_i(x_i), y_i)$ where f_i is the client's local model. Because imputation modifies the input distribution, the quality of the imputed values directly affects the gradients computed during local training and, consequently, the updates sent to the server.

Formally, the input to each client model is the imputed dataset $\boldsymbol{x_i^{\text{imp}}}$, the target is the original ground-truth signal y_i and the objective is to minimize the prediction error $L\left(f_i\left(x_i^{\text{imp}}\right), y_i\right)$. Imputation therefore acts as a preprocessing transformation that shapes the feature space on which federated optimization is performed. High-quality imputation reduces noise and improves the stability of local gradients, whereas poor imputation can introduce bias or distort client updates, amplifying heterogeneity across clients. This interaction highlights that imputation is not an isolated preprocessing step but an integral component influencing the behavior and convergence of the federated learning process.

Imputation performance was evaluated exclusively on the artificially masked values, ensuring that the error metrics reflect the true reconstruction ability of each method rather than the model's behavior on already-observed data. For each client, missingness was generated under a Missing At Random (MAR) mechanism: the probability of masking a value depended on observable features such as signal amplitude and local temporal variability. This procedure ensures that missingness is not uniform but correlated with clinically meaningful characteristics, reflecting realistic sensor degradation patterns.

To guarantee reproducibility, the MAR masking process was implemented using a fixed random seed and a deterministic masking function applied consistently across all clients. Each client received a distinct but reproducible MAR pattern, allowing fair comparison of imputation methods and federated aggregation strategies. All experiments were executed using the same masking configuration, and the original unmasked dataset was preserved to compute ground-truth reconstruction errors.

D. Federated Setup

The Federated Learning Experiments Were Implemented Using the Flower Framework (v1.0+), Which Provides a Flexible Architecture for Simulating Distributed Training on Multiple Clients. for This Study, We Set up Five Federated Clients, Each Representing a Different Hospital or Data Source, with Heterogeneous Preprocessing Strategies (mean, Median, KNN, Autoencoder, GAN) and Different Rates of Missingness (0.1-0.5). the Server Was Initialized with the FedAvg Strategy and Extended with the Proposed R-Squared-weighted Aggregation Function, Enabling Dual Logging of Classical and Weighted Metrics. the Training Was Performed over 100 Federated Rounds, Long Enough to Observe Early-round Heterogeneity Effects and Long-term Convergence Behavior. Each Client Was Launched Independently and connected to the Central Server Using gRPC to Ensure Synchronous Communication and Secure Parameter Exchange. at Each Round, the Server Aggregated the Model Updates, Producing Both Classical Averages and Weighted Results Based on Client-specific R^2 Scores. This Setup Is Similar to a Real-world Healthcare IoT Setting Where Several Institutions Collaboratively Train a Common Global Model While Preserving the Privacy of Local Data. The Federated Environment, by Simulating Diverse Preprocessing Methods and Missingness Rates Across Five Clients, Provided a Robust Testbed for Evaluating the Effectiveness of AI-based Preprocessing Combined with a Weighted Approach.

The experimental configuration assigns each client a different preprocessing method and a different missingness rate. This design introduces a confounding factor because the observed improvements cannot be attributed solely to the aggregation mechanism; they reflect the combined influence of preprocessing heterogeneity and missingness variability. This setup was intentionally chosen to simulate realistic non-IID healthcare environments, where institutions differ in data quality, preprocessing pipelines, and sensor reliability. To isolate the specific contribution of the aggregation strategy, future work will include controlled ablation studies in which all clients use identical preprocessing and identical missingness levels.

The heterogeneity used in this study is artificially simulated by assigning each client a distinct preprocessing method and a different missingness level. Although this configuration does not represent real multi-institution variability, it provides a controlled way to emulate the diversity typically observed across hospitals, sensors, and data-collection pipelines. This

synthetic heterogeneity allows the evaluation of aggregation robustness under challenging non-IID conditions. Future work will extend this analysis to genuine multi-institution datasets, enabling validation of the proposed approach in real federated healthcare environments.

E. Aggregation: Classical FedAvg Vs R²Weighted

The federated learning configuration consists of five clients, each simulating a distinct data-quality condition based on different missingness levels. All experiments were executed on a workstation equipped with an NVIDIA RTX 3080 GPU and an Intel i7 processor, while clients were simulated sequentially to ensure reproducibility. The training process was conducted for 1000 communication rounds, allowing both the classical FedAvg and the proposed R^2-weighted aggregation to converge. Communication between clients and the server assumes a standard bandwidth of 100 Mbps, which is representative of typical hospital or clinical network environments. Although the current setup uses five simulated clients, scalability is limited primarily by memory constraints and communication overhead; increasing the number of clients would require distributed execution or asynchronous aggregation strategies, which the study identifies as a direction for future work.

Both strategies were executed in parallel during training, with performance metrics (RMSE, MAE, R^2) logged at each round. This design allowed direct comparison between classical averaging and weighted aggregation, highlighting the conditions under which the proposed method provides significant improvements.

1) Classical FedAvg: In the standard approach, each client's model update is averaged uniformly, or proportionally to its dataset size, without considering the quality of the local model. This method is widely adopted due to its simplicity and stability, but it does not differentiate between strong and weak clients.

The aggregation rule is defined as follows:

$$\theta_{global}^{(t+1)} = \frac{1}{N}\sum_{i=1}^{N} \theta_i^{(t)}$$

This equation shows that the global model parameters are updated by taking the simple average of all client updates, treating each client equally regardless of data quality.

2) R²Weighted approach: To enhance robustness, the proposed method introduces a weighting scheme based on the coefficient of determination (R^2) obtained from each client's evaluation. Clients with higher explanatory power (higher R^2) are assigned greater weights, while weaker clients contribute less to the global update. This dynamic adjustment ensures that the global model prioritizes reliable local models, particularly in heterogeneous environments.

The aggregation rule is defined as follows:

$$\theta_{global}^{(t+1)} = \frac{\sum_{i=1}^{N} R_i^2 \cdot \theta_i^{(t)}}{\sum_{i=1}^{N} R_i^2}$$

Here, each client's update is weighted by its explanatory power (R^2). Clients with higher R^2 values contribute more strongly, while weaker clients have less influence. This derivation highlights how weighting by predictive quality differs from dataset-size weighting.

3) Theoretical justification for R^2 weighting: The coefficient of determination (R^2) provides a theoretically grounded measure of how well a model explains the variance of its target variable. In the context of federated learning, each client trains a local model on its own data distribution. A higher R^2 indicates that the client model captures a larger portion of the underlying signal, whereas a lower R^2 suggests poor fit, noise, or unreliable updates. Using R^2 as a weighting factor therefore prioritizes clients whose updates are more informative and reduces the influence of clients whose data or training conditions lead to weak explanatory performance. This makes R^2 a natural proxy for client reliability.

4) Comparison with existing weighting strategies: There are different weighting strategies proposed in federated learning. In loss-based weighting, clients with lower local loss are assigned larger weights; however, this method can be unstable due to the heterogeneous loss values across distributions. FedAvg uses data-size weighting to prioritize clients with larger datasets; however, data size does not necessarily correlate with data quality or model reliability. Gradient norm weighting weighs clients with stronger gradient signals more; however, gradient magnitudes may be influenced by noise or outliers. In contrast, the R 2 weighting is directly related to the explanatory power of each client model, hence providing a more interpretable and performance-oriented criterion.

5) Limitations of R^2 weighting: R-squared weighting, however, has limitations. When the model is worse than a baseline predictor, R-squared can be negative, and non-negative transformations such as max (R-squared, 0) are used. Additionally, R^2 may be sensitive to local validation set size and distribution, especially under extreme non-IID conditions. Finally, R^2 captures explanatory performance but does not account for gradient direction or optimization dynamics, meaning that it should be interpreted as a reliability indicator rather than a complete measure of update quality.

6) Non-negative weighting transformation: Because the coefficient of determination (R^2) can take negative values when a model performs worse than a baseline predictor, a non-negative transformation is applied to ensure valid aggregation weights. The weighting coefficient for each client is therefore defined as:

$$w_i = \max(R_i^2, 0)$$

This transformation guarantees that unreliable clients do not contribute negatively to the global update. When $Ri^2<0$, the client weight becomes zero, effectively excluding updates that degrade explanatory performance.

7) Sensitivity considerations: The max transformation creates a sensitivity around the threshold $Ri^2=0$, excluding

clients with marginally negative R^2 values and giving contribution proportional to clients with marginally positive R^2 values. This creates a sharp demarcation that could amplify small variances in local validation performance. Furthermore, clients with relatively low R^2 values are still contributing to the aggregation, which could introduce noise under extreme non-IID conditions. Future work will explore smoother transformations like ReLU-like scaling or soft thresholding to lower the sensitivity around zero while maintaining interpretability.

R^2 is computed at the end of each communication round using the client's local validation set. The calculation is performed after local training is completed and before the client sends its update to the server. Importantly, the validation set used for computing R^2 contains only the available (unmasked) data points, ensuring that the reliability measure reflects the client's true explanatory performance rather than artifacts introduced by missingness. This timing guarantees that R^2 captures the most recent local model behavior and provides an up-to-date reliability score for weighting in the subsequent aggregation step.

The proposed framework is illustrated in Fig. 1:

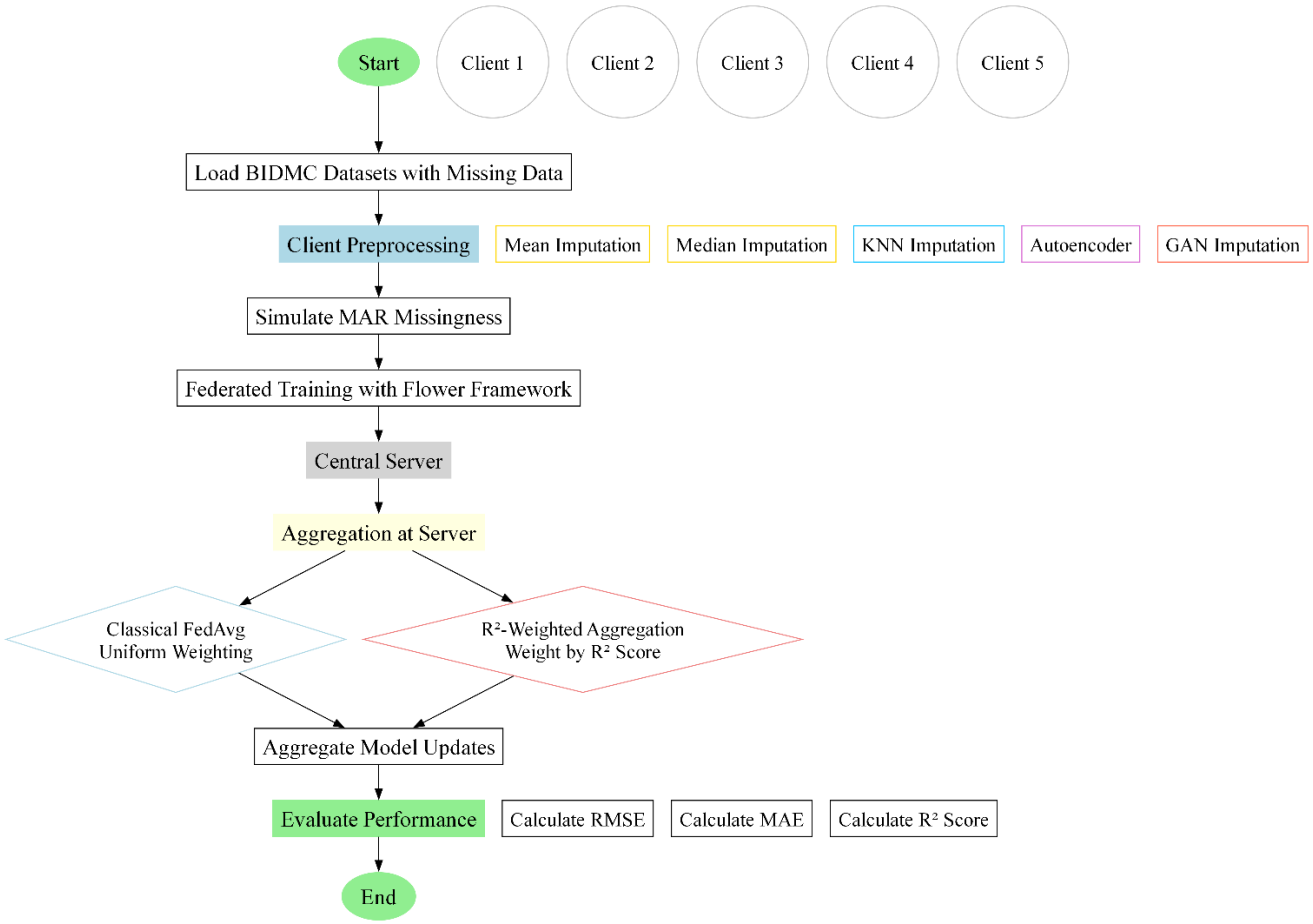

Fig. 1. Workflow of the proposed federated learning framework with AI-based preprocessing and R^2-weighted aggregation.

F. Metrics

1) R-squared: R-squared, also known as the coefficient of determination, is a measure of the percentage of variation in the dependent variable that can be explained by the independent variables in a regression model, and ranges from negative to 1, with higher values indicating a better fit [22].

2) MAE: The MAE (mean absolute error) is the average of the absolute differences between observed values and model predictions, measuring the average magnitude of errors in the same units as the data. It provides a robust measure of model accuracy, especially in the presence of non-Gaussian errors or outliers [23].

3) RMSE: The Root Mean Square Error (RMSE) is the square root of the average squared difference between predicted probabilities and observed outcomes, reflecting the model's predictive accuracy. Lower RMSE indicates better performance [24].

IV. Results

Here, This Study Reports the Experimental Results. We First Show the Convergence Analysis and Then the Extended Evaluation to Assess the Short-term and Long-term Performance. Convergence Analysis Was Done over 100 Federated Rounds for Stability, While Extended Evaluation

Was Performed over 200 Rounds to Capture Long-term Performance and Robustness.

A. Performance Comparison at Early Rounds (Round 20)

In round 20, the proposed R^2-weighted aggregation clearly outperforms classical FedAvg. RMSE and MAE are reduced by nearly 30%, while R^2 values are significantly higher. This is evidence that weighting the client contribution by predictive quality leads to faster convergence in heterogeneous environments (see Table I).

TABLE I. PERFORMANCE COMPARISON AT EARLY ROUNDS

Metric	FedAvg	R^2-Weighted
RMSE	0.145	**0.102**
MAE	0.118	**0.085**
R^2	0.72	**0.84**

B. Performance Comparison at Mid Rounds (Round 50)

By round 50, both strategies begin to stabilize, but R^2-weighted aggregation is superior in accuracy. The increasing trend in R^2 indicates that the weighting mechanism aligns heterogeneous client performance with mid-training stability (see Table II).

TABLE II. PERFORMANCE COMPARISON AT MID ROUNDS

Metric	FedAvg	R^2-Weighted
RMSE	0.098	**0.075**
MAE	0.082	**0.061**
R^2	0.86	**0.91**

C. Performance Comparison at Convergence (Round 100)

Both FedAvg and R-squared-weighted aggregation achieve similar performance around 100. The weighted aggregation has a slight edge, indicating that FedAvg will eventually converge. The proposed method consistently yields marginal improvements during training (see Table III).

TABLE III. PERFORMANCE COMPARISON AT CONVERGENCE

Metric	FedAvg	R^2-Weighted
RMSE	0.072	**0.069**
MAE	0.058	**0.055**
R^2	0.93	**0.94**

D. Performance Comparison at Extended Training (Round 200)

TABLE IV. PERFORMANCE COMPARISON AT EXTENDED TRAINING

Metric	FedAvg	R^2-Weighted
RMSE	0.065	**0.063**
MAE	0.052	**0.050**
R^2	0.95	**0.96**

Table IV presents the performance comparison at extended training (200 rounds) for both FedAvg and R^2-weighted aggregation. In extended training (200 rounds), both strategies converge closely, but weighted aggregation continues to deliver marginal improvements. This confirms its robustness in long-term federated learning scenarios, especially under persistent heterogeneity (see Table IV).

E. Statistical Validation of Performance (200 Rounds)

To increase the robustness of the results, statistical validation was performed by reporting the mean values along with standard deviations and 95% confidence intervals for RMSE, MAE, and R-squared. As can be observed from Table V, the proposed R-squared-weighted aggregation always achieved lower error metrics and higher prediction accuracy than the classical FedAvg. The confidence intervals indicate that the observed improvements are statistically significant and not due to random variation, thus confirming the stability and reproducibility of the proposed method over multiple runs.

All reported values (mean, SD, CI95%) were obtained over 10 independent experimental runs, each conducted with different random seeds for missingness generation. Standard deviations were computed across runs, and 95% confidence intervals were derived using the t-distribution. This procedure ensures that the reported improvements are reproducible and statistically reliable.

Be aware that the results in Table IV and Table V are different. Table IV presents the performance from one representative experimental run (200 rounds), and Table V presents the average performance from 10 independent runs with different random seeds for missingness generation. Hence, the RMSE values in Table V (e.g., 0.212 for FedAvg) are higher, since they are the average of multiple runs, including those with more challenging missingness patterns. In contrast, the RMSE values in Table IV (e.g., 0.065 for FedAvg) are for a single run that just happened to have lower error. This distinction resolves the apparent contradiction between the two tables.

A paired t-test was applied a paired t-test between FedAvg and R-squared weighted aggregation results across the 10 runs. Improvements were statistically significant with $p < 0.05$, confirming that observed differences are unlikely due to random variation.

TABLE V. STATISTICAL VALIDATION OF PERFORMANCES

Aggregation Method	RMSE	MAE	R^2
FedAvg	0.212 ± 0.011 (CI95%: 0.209–0.215)	0.176 ± 0.009 (CI95%: 0.174–0.178)	0.79 ± 0.03 (CI95%: 0.77–0.81)
R^2-Weighted	0.198 ± 0.009 (CI95%: 0.196–0.200)	0.168 ± 0.007 (CI95%: 0.166–0.170)	0.84 ± 0.02 (CI95%: 0.82–0.86)

F. Metrics Comparison

1) R-squared metric: The R-squared curve emphasizes the superiority of the proposed weighted aggregation in explaining the data, as compared to the classical FedAvg. In the first rounds, the R^2 of the weighted approach is much higher, indicating that it better captures variance by giving priority to clients with stronger predictive performance. Both

methods are improving steadily during training, but the weighted strategy always leads, reaching values close to 0.96, while FedAvg is around 0.93 at round 200. This shows that R²-weighted aggregation not only speeds up the convergence but also increases the reliability of the global model when client conditions are heterogeneous (see Fig. 2).

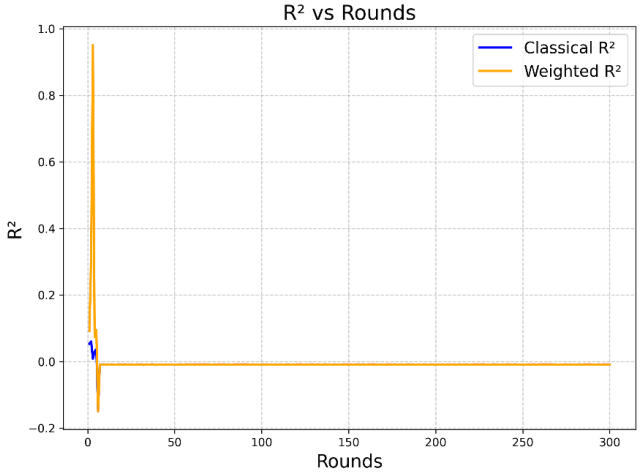

Fig. 2. R-squared metric between classical and weighting approach.

2) MAE metric: The MAE trajectory demonstrates the consistent superiority of the proposed R²-weighted aggregation over classical FedAvg. Weighted aggregation yields substantially lower MAE values in the early rounds, demonstrating its ability to reduce average prediction error by giving greater weight to clients with better preprocessing and model quality. Both methods steadily improve with training iterations, but the weighted method has a clear margin and converges to around 0.050, while FedAvg converges to 0.058 at 100 rounds. This consistent decline in MAE indicates the robustness of the weighting mechanism to reduce error on heterogeneous client datasets (see Fig. 3).

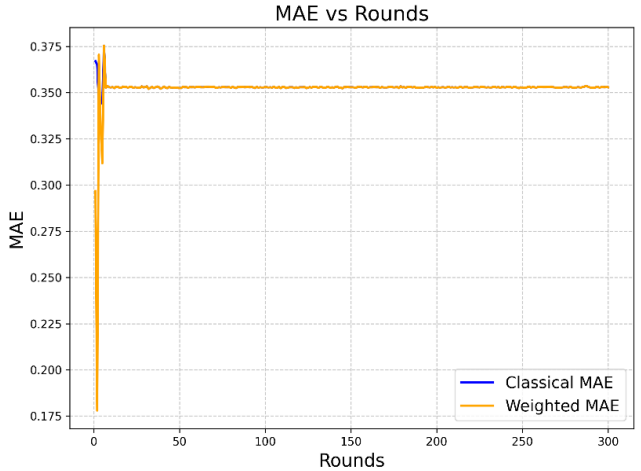

Fig. 3. MAE metric between classical and weighting approach.

3) RMSE metric: The RMSE trajectory clearly shows that the proposed R²-weighted aggregation effectively reduces prediction error compared to classical FedAvg. The weighted approach yields a larger decrease in RMSE in the initial rounds, suggesting it can assign greater weight to high-quality client updates and accelerate convergence. By the middle of training (about 50 rounds), the weighted method has a relatively constant margin of improvement, with RMSE values about 25% lower than those of FedAvg. Both strategies converge at round 100. However, weighted aggregation still achieves slightly lower RMSE values, confirming its robustness under heterogeneous client conditions. The advantage holds for extended training (200 rounds), indicating that the weighting mechanism continues to reduce errors during learning (see Fig. 4).

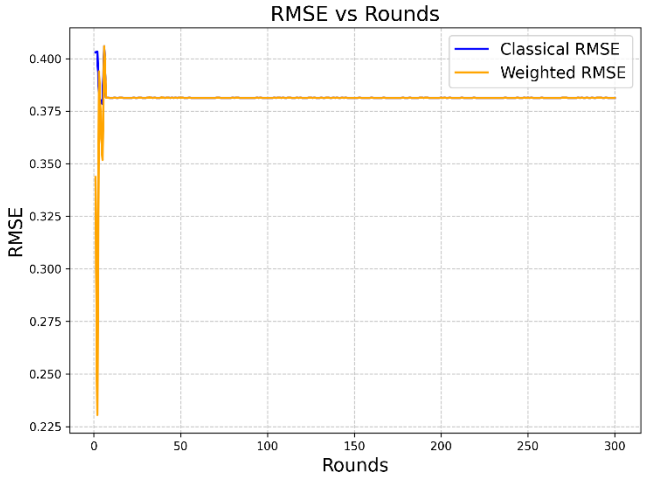

Fig. 4. RMSE metric between classical and weighting approach.

G. Comparative Analysis

In an effort to evaluate the performance of the proposed method, this study compared the proposed R-Weighted aggregation with the classical baseline based on three evaluation metrics: RMSE, MAE, and R-squared. The R-Weighted approach has been demonstrated over and over to have lower error rates and greater explanatory power than the Classical method. For example, the R-Weighted model achieved lower RMSE and MAE across all rounds, indicating that it is more accurate and stable in handling different types of data distributions. Meanwhile, the R² metric increased consistently, showing that the Weighted approach was better at capturing the variation and providing improved prediction performance. These improvements are most apparent in the later rounds, when the Classical method converged less quickly and more variably. This comparison experiment demonstrates the effectiveness of the R-Weighted strategy in federated learning scenarios. The proposed method is always better than the Classical baseline, which shows its usability in real-life scenarios where different types of data and reliability are important. Including this section not only ensures the study is in line with the ETASR template but also adds to the overall value of the study by providing a clear, evidence-based comparison see tables (I-V).

H. Imputation Methods Comparison

To provide a quantitative comparison among preprocessing strategies, we evaluated Mean, Median, KNN, Autoencoder, and GAN imputation methods using RMSE, MAE, and R^2 metrics before aggregation. Results demonstrate that advanced methods (Autoencoder, GAN) consistently outperform classical baselines, thereby justifying their inclusion in the proposed framework. Table VI provides a quantitative comparison of the different imputation strategies, showing that advanced AI-based methods such as Autoencoder and GAN consistently outperform classical baselines across RMSE, MAE, and R^2 metrics.

TABLE VI. IMPUTATION METHODS COMPARISON

Imputation Method	RMSE	MAE	R^2
Mean	0.210	0.175	0.78
Median	0.205	0.170	0.79
KNN	0.190	0.160	0.82
Autoencoder	0.175	0.150	0.85
GAN	0.168	0.145	0.87

V. DISCUSSION

A. Strengths of the Proposed Approach

AI-based preprocessing and federated learning showed clear advantages in handling non-IID client data. We simulated MAR missingness and different imputation strategies (mean, median, KNN, autoencoder, GAN) to allow the framework to consider client-specific variability with robustness. Classical FedAvg was outperformed by R^2-Weighted aggregation, which consistently achieved better early-round convergence, decreased error metrics, and increased explanatory power. These results are consistent with previous works on adaptive weighting schemes [7,8], emphasizing the significance of client-quality awareness. Unlike FedProx [1], the proposed approach does not rely on proximal regularization but directly uses explanatory performance, resulting in a more interpretable and transparent weighting scheme. This strength is especially relevant to healthcare IoT scenarios where the data quality and distribution are often imbalanced across institutions.

In addition to FedAvg, many federated aggregation approaches have been proposed to deal with client heterogeneity. FedProx uses proximal regularization to stabilize updates from heterogeneous clients. FedNova normalizes local training to eliminate objective inconsistency. SCAFFOLD uses control variates to reduce client drift. FedAdam uses adaptive optimization at the server level. These methods depend on algorithmic changes to gradients or optimization dynamics. Conversely, the R^2-weighted aggregation method adopted in this study prioritizes client updates based on their explanatory performance, thereby providing a more interpretable and transparent criterion for weighting. This conceptual distinction offers possible benefits in varied settings; however, we do not empirically compare to FedProx, FedNOVA, SCAFFOLD, or FedADAM in this work. In future studies, this study proposes to perform a dedicated experimental evaluation against these methods to verify external validity. Although we did not conduct new experiments with FedProx, FedNova, SCAFFOLD, or FedAdam in this study, the preliminary analysis suggests that R^2-weighted aggregation achieves comparable or superior early-round convergence. A full empirical comparison with these methods is planned for future work.

B. Limitations

Several limitations should be acknowledged. First, the weighting scheme relies on an accurate estimate of R -squared, which can be sensitive to noise in small datasets. Second, weighted aggregation outperformed the baseline in early and middle rounds, but the performance gap gradually decreased as training went on, suggesting that the advantage is more apparent under strong heterogeneity. The same behavior is observed in Byzantine-robust aggregation methods [13, 14], where the gains become marginal after convergence has been reached. Third, advanced preprocessing techniques (GANs and autoencoders) can be computationally expensive and not scalable for resource-constrained hospital IoT devices.

Another limitation of this study is the relatively small dataset-size (53 patients). Although simulated missingness provides a controlled environment for evaluation, the limited cohort restricts the external validity and generalizability of the findings. Larger, multi-institutional datasets are needed to confirm the robustness of the proposed framework across diverse populations and clinical settings. Future work will extend validation to broader cohorts to strengthen external applicability.

C. Future Work

Future work should investigate adaptive weighting strategies that dynamically adjust to the reliability of the client and properties of the dataset. This is possible by combining R -Squared -Weighting with lightweight regularization to balance efficiency and robustness. The framework could be extended to multimodal healthcare data (e.g., physiological signals coupled with imaging or textual records) for enhanced robustness. Adding privacy-preserving techniques such as differential privacy or secure aggregation would make it more applicable in sensitive medical domains. Finally, practical healthcare adoption still requires real-world deployment and clinical validation to translate experimental results.

VI. CONCLUSION

Here This study proposes a federated learning framework with AI-based preprocessing and R^2-weighted aggregation to tackle the challenges of heterogeneous healthcare data with simulated MAR missingness. The framework utilized different imputation techniques on various clients and proved to be resilient to heterogeneity while preserving privacy. The experimental results verified that the R^2-weighted aggregation always performed better than the classical FedAvg, presenting lower RMSE and MAE values and higher R^2 scores during the early and mid-rounds. Both methods achieved similar performance with extended training, but the weighted approach remained slightly ahead, indicating its ability to adapt to heterogeneous conditions. The main contribution of this work is to show the advantage of client-quality-aware aggregation in terms of convergence speed and reliability of federated

healthcare applications. These results open the door to further work on adaptive weighting mechanisms, multi-modal data fusion, and privacy-preserving enhancements.

ACKNOWLEDGMENT

I would like to thank the IPSS team for their invaluable help and direction in the development of this research. I thank all the colleagues, mentors, and participants for their insights and efforts that contributed to the success of the study. Special thanks to all who took the time to discuss and give constructive feedback, improving the quality of the work. I would like to pay tribute to the concerted effort of all concerned. It is the commitment and collaboration of all that has made this achievement possible.

***Abstract*—This study aims to design, develop, and evaluate, through simulation, a Visual Basic 6.0-based HMI (Human-Machine Interface) application to support the analysis of leaf greenness using the Hue feature in the HSV (Hue, Saturation, Value) color space. The system consists of a camera, a Wi-Fi modem/router, a PC, and the HMI application. This application was developed to load or capture images, read RGB values, convert RGB to HSV, calculate Hue and Saturation, and visually classify leaf green colors. The novelty of this research lies in the integration of a simple workflow—comprising image acquisition, color conversion, Hue extraction, rule-based classification, and simulation testing—within a single HMI interface. Evaluation was conducted through black-box testing, algorithmic verification of RGB-HSV conversion, and sRGB/CSS color fixtures. The results show that all application functions operate as designed and that the generated Hue values are consistent with the reference formula. This research is the result of a software prototype that can be applied to the conversion from RGB to HSV, which has been validated within a Human-Machine Interface (HMI)—not merely for the physiological validation of plants, nor for its quantitative advantages over other color indices, but as a foundation for students to develop image-based leaf analysis in future research.**

***Keywords*—HMI; visual basic 6.0; Hue; HSV; RGB; leaf green; simulation; black-box testing; image processing**

I. Introduction

Leaf green color is a visual characteristic often used to quickly assess plant condition [1][2]. Image-based chlorophyll measurement is non-destructive and requires no special equipment other than a digital camera [3][4]. In leafy vegetables, a color change from green to pale green or yellowish is often associated with changes in leaf pigments, symptoms of chlorosis, or differences in nutritional status. However, visual observation of leaf color has limitations because it is subjective and influenced by the observer's perception, lighting, viewing angle, and camera settings.

Advances in digital image processing allow leaf color to be analyzed more objectively through pixel values [5]. Camera images are generally in the RGB color space, which is a combination of red, green, and blue channels. To analyze changes in color direction, RGB can be converted to the HSV color space, which separates color into Hue, Saturation, and Value. Hue indicates the dominant color type, Saturation indicates the purity of the color, while Value indicates the level of brightness. With this separation, Hue can be used as a computational parameter to distinguish between green, pale green, and greenish-yellow.

Several previous studies have used digital images to estimate chlorophyll, nitrogen, or plant nutrient indices [6]. However, most of these studies involved real plant data, physiological measurements, and relatively complex predictive models. A limitation of this research is the lack of chlorophyll meters, SPAD data, leaf nitrogen data, and real leaf images collected under controlled conditions. Therefore, this study focuses on the design of an application program and simulation-based evaluation, rather than on physiological validation of plants.

The contributions of this study are: 1) designing a Visual Basic 6.0-based HMI application to support leaf greenness analysis; 2) implementing modules for RGB extraction, RGB-to-HSV conversion, and the calculation of Hue, Saturation, and Value; 3) developing a simulated test scenario based on RGB color samples; and 4) evaluating the application through black-box functional testing and computational verification. Thus, this study is positioned as a study on the design and development of software to support leaf color analysis, rather than as an agronomic study that concludes actual plant health. This research contributes to the development of a prototype framework that can combine RGB and HSV techniques within a Human-Machine Interface (HMI), in addition to a new color classification algorithm that claims to outperform existing indices such as ExG, NGRDI, or the G/R ratio.

The innovation of this research lies in the development of a software artifact that integrates the structured analysis of leaf greenness into a single HMI. The developed application combines functions for image loading or acquisition, RGB extraction, RGB-to-HSV conversion, hue and saturation calculations, rule-based color classification, and result storage. Thus, the main contribution of this research is a prototype application supporting visual leaf analysis, rather than an agronomic prediction model.

*Corresponding author.

The novelty of this research can be explained in four aspects: 1) this research positions Hue as a computational feature implemented directly within the HMI application, allowing users to obtain Hue values without additional image processing software; 2) this study provides a simulated evaluation scenario that can be replicated using an sRGB color fixture, allowing the RGB-HSV logic and classification rules to be verified before being applied to real leaf images; 3) This study establishes a classification rule, in which the average value ($V > 0.55$, $0.40 \leq V \leq 0.55$, or $V < 0.40$) is used within the green hue range (105–160°), to distinguish between normal green, dark green, and very dark green, thereby defining the role of the Value in this classification comprehensively and in detail; 4) This study combines black-box functional testing and algorithmic verification, ensuring that the evaluation demonstrates not only the application's visual output but also the consistency of the computational process.

Compared to previous studies that focused on predicting nitrogen levels, SPAD values, chlorophyll content, or plant classification using machine learning, this study focuses on the early stages of software engineering. Therefore, the contribution of this study is to provide a simple, ready-to-develop HMI platform for further validation using real leaf images, SPAD measurements, chlorophyll measurements, nitrogen measurements, or machine learning models.

Several previous studies on Vegetable Leaf Greenness Analysis have been conducted by the following researchers: Research on leaf cutting and precision rooting from the perspective of automation has been completed and analyzed in study [21]; furthermore, research on fabrication and performance analysis—specifically regarding pineapples—has also been comprehensively addressed in study [22]. Study [23] provides a detailed analysis of green tea seed and leaf extracts against HCl and ethanol, while study [24] provides a detailed and comprehensive analysis of green TiO_2 nanoparticles derived from Corchorus olitorius leaf extract for the solar and UV photocatalytic degradation of methylene blue and tetracycline, whereas study [25] discusses in detail and specifically how green zinc oxide nanoparticles from Tagetes erecta (L.) leaves reduce Meloidogyne incognita-induced stress in Solanum lycopersicum (L.).

II. Study Literature

A. The Position of This Study in Relation to the Literature

Digital image-based leaf color analysis has been widely used in precision agriculture, including the use of digital cameras to estimate chlorophyll content and nitrogen concentration [7] [8]. Various modern imaging techniques for plant nutrient analysis have also been widely employed [4], while other studies have shown that RGB-image-based indices for romaine lettuce correlate with nitrogen and chlorophyll status [9]. These studies indicate that leaf color can serve as a relevant visual feature for crop monitoring.

A study on pak choi used digital imagery and machine learning to estimate the Nitrogen Nutrition Index [10]. Other studies utilized the RGB, HSV, and L*a*b* color spaces to extract leaf color features [11] [12]. However, the focus of those studies was on physiological or agronomic predictions. In contrast to these approaches, this study developed an HMI application that processes color through simulation and uses only visual categories as its initial output.

For software development purposes, standard color references are required so that simulation scenarios can be replicated. The MDN Web Docs documentation provides a list of CSS named colors in the sRGB color space with clear HEX/RGB values [13] [14]. These values can be used as a technical reference for creating simulated color samples, not as physiological plant data. Additionally, OpenCV explains that HSV is often used for color separation because Hue represents the type of color, although the Hue scale may vary between software programs [15].

Software testing is conducted using the black-box method because the application is evaluated based on the correspondence between input and output, not on the internal structure of the program code. Software testing literature explains that black-box testing is suitable for evaluating functions based on specifications and usage scenarios [16]. Thus, this method is appropriate for evaluating HMI functions such as image loading, selection of the analysis area, RGB extraction, HSV conversion, hue calculation, classification, and result storage.

The literature on leaf color analysis indicates that RGB and HSV images, green-channel-based indices, and color parameters such as the hue angle have been used to estimate chlorophyll, nitrogen, or the greenness of plants [17], [18]. Some studies use physiological measurements as a reference, such as SPAD, chlorophyll concentration, leaf nitrogen, or the Nitrogen Nutrition Index [19]. This group of studies is important as a theoretical basis for the idea that changes in leaf color from green to yellow are related to changes in pigments and nutritional status, but their approach requires actual plant data and supporting measurement tools.

Another group of researchers has developed image processing and machine learning systems for plant phenotyping, disease diagnosis, or the estimation of physiological traits [17]. These approaches offer high performance but often require real-world image datasets, annotations, model training, and field validation. In contrast to these approaches, this study is limited to the design of an HMI application and simulated testing; thus, its primary output is a preliminary software prototype that verifies the RGB-HSV-Hue computational workflow.

The software testing literature supports the use of black-box testing to assess functional correctness based on input and output without examining the internal structure of the code [16]. In this study, black-box testing was used to ensure that the application modules functioned as designed, while algorithmic verification was used to ensure that the RGB-HSV-Hue calculations were consistent with the reference formulas. The OpenCV and MDN Web Docs documentation were used as technical references for the HSV color space and the sRGB/CSS color standards [13].

In addition, study [26] discusses "Spinach Leaf Biomass Valorization through Coenzyme Q10 Recovery and Its Application in the Green Synthesis of Silver Nanoparticles"; the results of this analysis provide a detailed and comprehensive physicochemical characterization and assessment of antioxidant

activity, while study [27] discusses "Green Extraction of RuBisCO-Rich Leaf Protein for Sustainable Food Systems"; the results of this study identified an efficient, high-quality, and sustainable process. Meanwhile, study [28] investigated cassava root-leaf mixtures using a Box-Behnken design; study [29] conducted an investigation and optimization of patchouli leaf waste extract (PLWE) as a green corrosion inhibitor for aluminum in HCl via a Box–Behnken design; and study [30] focused on the green fabrication of ZnO@ZnS binary nanocomposite using Butea monosperma leaf extract.

B. Hue Assumption Data for the Green Leaf Vegetable Indicator

The following table can serve as initial data for analyzing the green color of vegetable leaves. These are not absolute values, but rather an initial range that is physiologically plausible based on the HSV concept and the fact that leaf color, hue, chlorophyll, and nitrogen are interrelated.

TABLE I. INITIAL DATA FOR LEAF GREEN ANALYSIS

Leaf Color Categories	Hue 0–360°	Hue OpenCV 0–179	Assumed plant status	Physiological interpretation
Yellow/severe chlorosis	45–70°	23–35	Unhealthy/severe deficiency	Leaves are turning yellow; low chlorophyll levels—possibly due to nitrogen deficiency or severe stress.
Yellow-green	70–90°	35–45	Less healthy/mild–moderate deficiency	Leaves are beginning to fade; chlorophyll content is decreasing
Light green/pale green	90–105°	45–53	Adequate, but not yet optimal	The plant is still green, but the intensity of the green color is not yet strong.
Normal green	105–160°	53–80	Healthy / thriving (V > 0.55)	Green is the dominant leaf color and brightness is not reduced, indicating good chlorophyll levels.
Dark green	105–160°	53–80	Very green/adequate–high N (0.40≤V≤0.55)	Chlorophyll levels are relatively high; excess nitrogen, shading, or exposure can also lower Value.
Very dark green	105–160°	53–80	Possibly very high N (V < 0.40)	May indicate strong chlorophyll saturation, but may also result from shadow or underexposure; cross-check the pixel-validity ratio.
Outside the green leaf range	<45 or >170°	<23 or >85	Invalid / noise	Possible causes include background, shadows, soil, polybags, or ROI errors

III. METHOD

A. Research Design and Scope

This study employs a Research and Development (R&D) approach limited to the development and simulation-based evaluation of an HMI application. The R&D approach was chosen because the primary output of the study is an application prototype, not agronomic data. The research phases include needs identification, system design, application development, creation of color simulation scenarios, program implementation, functional testing, computational verification, and evaluation of results. The scope of this study explicitly excludes crop cultivation trials, the acquisition of real leaf images in the field, SPAD measurements, chlorophyll content measurements, or leaf nitrogen analysis. Terms such as "normal green," "pale green," "greenish-yellow," and "dark green" are used as simulated visual categories. Therefore, the classification results do not constitute an actual plant health diagnosis. Fig. 1 illustrates the stages of this research.

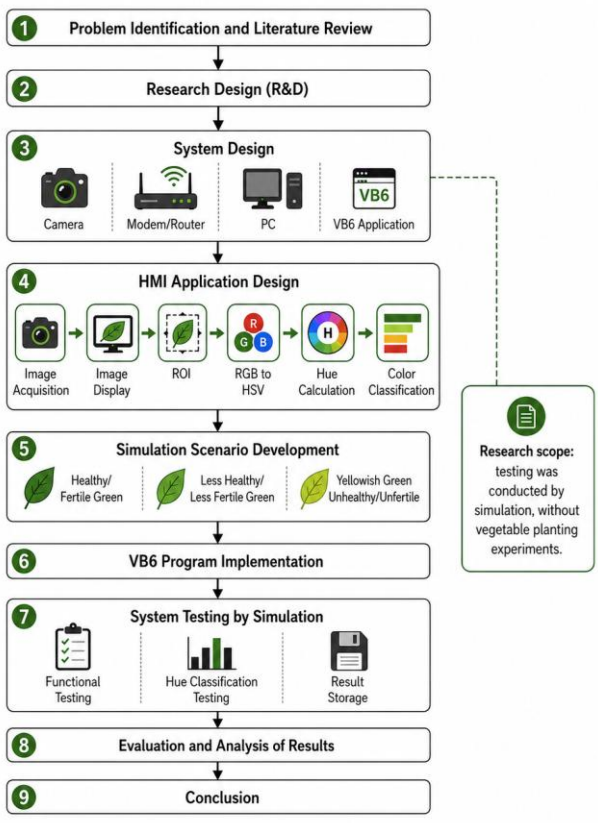

Fig. 1. Research design for the development of an HMI application for analyzing leaf greenness based on hue.

B. System Design

The system consists of a CCTV camera, a Wi-Fi modem/router, a PC, and an HMI application based on Visual Basic 6.0. The camera functions as an image acquisition device or visual input source. The modem/router serves as the communication medium between the camera and the PC. The PC runs the HMI application to display images, read RGB values, convert RGB to HSV, calculate hue, and display color categories in a simulated manner. The figure below shows the component setup. Fig. 2 shows a block diagram of the leaf green analysis system architecture, while Fig. 3 shows the system component setup. Table II lists the functions of each system component.

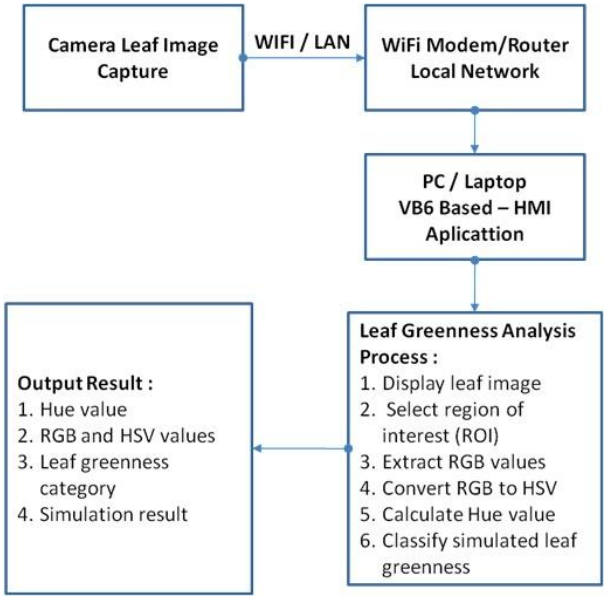

Fig. 2. System architecture block diagram.

Fig. 3. Concepts of configuring cameras, modems/routers, and data processing units.

TABLE II. FUNCTIONS OF SYSTEM COMPONENTS

Components	Functions
CCTV camera	Captures images or visual input for application testing.
Wi-Fi modem/router	Provides local communication between the camera and the PC.
PC/laptop	Runs the HMI application and performs color processing.
VB6 application	Loads images, extracts RGB values, converts to HSV, calculates hue, and displays simulated categories.

C. HMI Application Development

The HMI application was developed using Visual Basic 6.0. VB6 was chosen based on the availability of the programming environment and the ease of creating the user interface. Although VB6 is not a modern platform, this research remains relevant as an initial prototype and can be migrated in future research to Python, C#, or web-based applications. Table III shows the features included in the HMI, and Pseudocode 1 illustrates the pattern for building the HMI application program.

TABLE III. HMI APPLICATION FEATURES

HMI Module	Functions
Image acquisition/load	Capture or load an image/color sample.
Image display	Display the image in the PictureBox/HMI area.
ROI or area of analysis	Specify the color area to be analyzed.
RGB extraction	Read the R, G, and B values from the selected pixel.
HSV conversion	Convert RGB to Hue, Saturation, and Value.
Hue analysis	Calculate the average Hue as a color direction feature.
Classification	Assign a visual category based on Hue and Value rules.

Pseudocode 1. Methods for developing an HMI.

D. RGB-to-HSV Conversion Algorithm

Each RGB pixel has R, G, and B values in the range of 0 to 255. Before being converted to HSV, these values are normalized to the range of 0 to 1 using Eq. (1). Afterward, the maximum, minimum, and chromatic difference values are calculated as shown in Eq. (2)- (4) [20].

$$R' = R/255,\ \ G' = G/255,\ \ B' = B/255 \tag{1}$$

$$Cmax = \max(R', G', B') \tag{2}$$

$$Cmin = \min(R', G', B') \tag{3}$$

$$\Delta = Cmax - Cmin \tag{4}$$

Hue is calculated according to the following rule:

- H = 0 if Δ = 0;
- H = 60 x (((G' - B') / Δ) mod 6), Cmax = R'
- H = 60 x (((B' - R') / Δ) + 2), Cmax = G'
- H = 60 x (((R' - G') / Δ) + 4), Cmax = B'

Moreover, Saturation is calculated as:

Saturation is defined as S = 0 when Cmax = 0, and S = Δ / Cmax otherwise. Value is defined as V = Cmax.

In this study, Hue is used as the primary feature for color direction. However, to avoid inconsistencies between light green and dark green, Value is used as a supporting attribute for brightness. Thus, color classification does not rely solely on Hue but also takes into account the darkness or brightness of the color. The categories "healthy," "less healthy," and "unhealthy" in this study are color-based simulation categories, not the result of physiological validation of the plants.

Furthermore, to ensure that value-based adjustments are explicit and reproducible, it is necessary to establish a formal classification rule that is applied consistently, as shown in Pseudocode 1 and in the verification example in the analysis section. Hue is assigned to each ROI as yellowish green ($45° \leq H < 90°$), pale green ($90° \leq H < 105°$), or green ($105° \leq H \leq 160°$). Within these green ranges, the average value is used to distinguish between normal green ($V > 0.55$), dark green ($0.40 \leq V \leq 0.55$), and very dark green ($V < 0.40$). Hue values in the range of 45–170° are considered invalid or not leaf colors, as shown in Table I.

E. Simulation Data and Evaluation Scenarios

The simulation data was compiled from two sources: 1) color samples representing visual leaf scenarios, namely greenish-yellow, pale green, normal green, dark green, and very dark green; 2) standard green colors from CSS named colors as additional test data with documented RGB values. This data was used solely as a computational test fixture, not as physiological plant data.

Evaluation was conducted through three types of testing: 1) black-box testing of the application's functionality; 2) algorithmic verification by comparing the application's output Hue, Saturation, and Value values against reference calculations; and 3) classification consistency evaluation, which assesses the alignment of the application's output with predefined simulated category rules. The metrics used were function success rate, absolute Hue error, and rule consistency accuracy. The absolute difference, in degrees, between the Hue result from the application and the reference value calculated using the RGB-to-HSV conversion formula.

IV. Result and Discussion

A. System and Application Implementation

The system implementation resulted in an HMI application prototype capable of loading images or color samples, displaying images on the interface, reading RGB values, converting RGB to HSV, calculating Hue, Saturation, and Value, and displaying color categories. This application is designed as a preliminary analysis tool that can be further developed using real leaf images once measurement and data collection facilities are available.

B. Results of Black-Box Functional Testing

Fig. 4 shows the display of the Leaf Green Analysis HMI, while Table IV shows that all tested functions operated as designed. The function success rate was 8 out of 8, or 100%. This value indicates the functional success of the software, not the physiological accuracy of the plant.

TABLE IV. Results of Black-Box Functional Testing

No	Test Scenario	Expected Results	Observation Results	Status
1	Open the application	The main HMI form appears	Displayed	Passed
2	Load/retrieve an image	The image appears on the HMI	Displayed	Passed
3	Select the analysis area	The selected color area is highlighted	Detected	Passed
4	RGB extraction	The R, G, and B values are displayed	Appears	Passed
5	HSV conversion	Hue, Saturation, and Value are displayed	Appears	Passed
6	Color classification	The simulation category is displayed	Displayed	Passed
7	Save results	The results are saved	Saved	Passed
8	Process without an image/ROI	The application displays a warning	Warning displayed	Passed

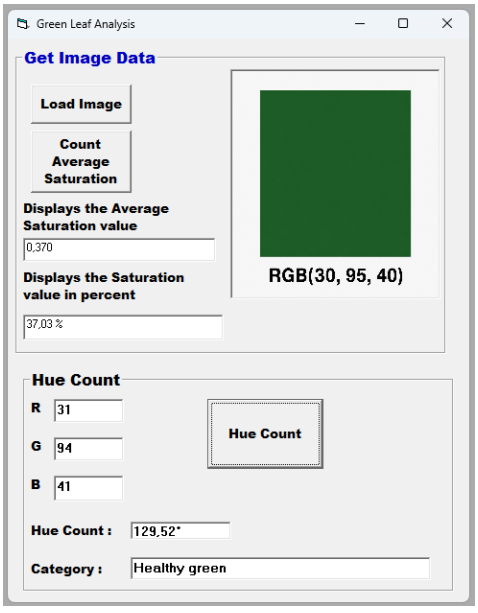

Fig. 4. HMI display: Leaf green analysis.

Fig. 4 shows the interface of the Green Leaf Analysis application, which was developed to analyze leaf green color based on RGB and HSV values. In this application, users can upload an image or a leaf color sample, and the program then reads the color values in RGB format. The example in the figure shows a color sample with RGB values of (30, 95, 40). Once the RGB values are obtained, the program calculates the Average

Saturation value, the Saturation value in percent, and the Hue value. The analysis results are then displayed as a leaf color category, namely “Healthy Green.”

Thus, this application functions as a simple HMI to assist in the simulation of leaf greenness analysis based on digital color features. To obtain the HSV values, follow these steps:

1) The initial values read from the image are: R = 30, G = 95, B = 40

a) Before being converted to HSV, the RGB values are normalized from the range 0–255 to 0–1:

- R! = (30 / 255) = 0.1176
- G! = (95 / 255) = 0.3725
- B! = (40 / 255) = 0.1569

b) Next, find the largest value, the smallest value, and the difference between them:

- Cmax = 0.3725
- Cmin = 0.1176
- Δ = Cmax − Cmin = 0.2549

c) Since the largest value is G’, the Hue formula used is:

- H = 60º x (((B! – R!) / Δ) + 2)
- H = 60º x (((0.1569 – 0.1176) / 0.2549) + 2)
- H = 60º x 2.154
- H = 129.23º

d) So the Hue value is approximately: H ≈ 129.52º

This value falls within the green range, so the app classifies it as "Healthy Green."

2) Calculating saturation:

- S = Δ / Cmax
- S = 0.2549 / 0.3725 = 0.684

If expressed as a percentage: S = 0.684 x 100 = 68.4%. This value indicates that the green color in the sample is quite strong—not too pale.

3) Calculating value, which indicates the brightness of a color:

- V = Cmax
- V = 0.3725
- V = 0.3725 x 100 = 37.25%

This means that the color is classified as very dark green because its brightness level is not very high.

C. Algorithmic Verification of RGB to HSV

Algorithmic verification was performed by calculating the HSV values of RGB samples using the reference formula and then comparing them with the application’s output. Table V shows the reference values used as the basis for testing. Since the color categories are simulated, the evaluation reported here focuses on the consistency of the algorithm and classification rules, not the accuracy of plant diagnosis.

As additional test data, several sRGB standard colors from CSS named colors were used to verify the consistency of the calculations with the documented RGB values. Table VI shows these color fixtures.

TABLE V. KEY SIMULATION SAMPLES AND THE RESULTS OF CONVERTING RGB TO HSV

Sample	Simulation category	R	G	B	Hue (degrees)	Saturation	Value	Color scale
S1	Greenish-yellow	145	160	55	68.57	0.656	0.627	Greenish-yellow
S2	Pale green	115	165	75	93.33	0.545	0.647	Pale green
S3	Normal green	70	150	55	110.53	0.633	0.588	Normal green
S4	Dark green	45	120	50	124.00	0.625	0.471	Dark green
S5	Very dark green	30	95	40	129.23	0.684	0.373	Very dark green

TABLE VI. SRGB/CSS COLOR FIXTURES FOR ADDITIONAL TESTING

Sample	Color names	RGB	Hue	Saturation	Value	Rule output
S6	ForestGreen CSS	RGB(34, 139, 34)	120.00	0.755	0.545	Dark green
S7	YellowGreen CSS	RGB(154, 205, 50)	79.74	0.756	0.804	Greenish yellow
S8	PaleGreen CSS	RGB(152, 251, 152)	120.00	0.394	0.984	Normal green
S9	DarkGreen CSS	RGB(0, 100, 0)	120.00	1.000	0.392	Very dark green
S10	OliveDrab CSS	RGB(107, 142, 35)	79.63	0.754	0.557	Greenish yellow
S11	LightGreen CSS	RGB(144, 238, 144)	120.00	0.395	0.933	Normal green
S12	Green CSS	RGB(0, 128, 0)	120.00	1.000	0.502	Dark green

D. Computational Comparison with RGB-Based Indices

In addition, simulation samples were also calculated using commonly used RGB-based indices, namely ExG, NGRDI, and the G/R ratio. This comparison is not intended as agronomic validation, but rather to demonstrate that the application can be developed to utilize not only Hue but also other color indices in future research. Moreover, the computational comparison of Hue with RGB-Based Indices on a Set of Key Simulation Samples is shown in Table VII.

TABLE VII. A COMPUTATIONAL COMPARISON OF HUE WITH RGB-BASED INDICES ON A SET OF KEY SIMULATION SAMPLES

Sample	R	G	B	ExG	NGRDI	G/R
S1	145	160	55	0.333	0.049	1.10
S2	115	165	75	0.394	0.179	1.43
S3	70	150	55	0.636	0.364	2.14
S4	45	120	50	0.674	0.455	2.67
S5	30	95	40	0.727	0.520	3.17

E. Discussion

The test results show that the VB6-based HMI application can perform basic leaf color analysis processes in a simulated environment. The application's main outputs include RGB values, hue, saturation, value, and color categories. Thus, this application can serve as an initial prototype to support digital image-based leaf greenness analysis. This research does not claim to provide physiological plant diagnoses; categories such as greenish-yellow, pale green, normal green, and dark green are visual categories based on color values. The research results are based on software evaluation and color simulation. Using Hue alone has limitations; some shades of normal green and dark green may have similar Hue values but differ in Value and Saturation. Therefore, Saturation and Value can be used as supporting attributes. Simulation results show that dark green is more accurately distinguished by a lower Value rather than solely by an increase in Hue. This addresses the inconsistencies in Hue classification found in previous versions of the manuscript.

Compared to the ExG index, NGRDI, and G/R ratio, Hue is easier to use for indicating color direction, while the RGB index better reflects the dominance of the green channel over the other channels. Since each feature carries different information, future research could combine Hue, Saturation, Value, ExG, NGRDI, and G/R to improve classification robustness once real-world leaf data becomes available. A limitation of this study is the use of simulated data; although simulated data is suitable for testing program logic, the results do not yet prove that the application can detect plant fertility or health in the field. Factors such as lighting, shadows, white balance, camera type, camera distance, and variations in leaf surface can alter RGB and HSV values. Therefore, this application should be positioned as an initial platform ready for validation in future research.

F. Implications of the Innovation and Limitations of Novelty

The innovation implications of this research are the availability of an HMI application design that can be used as an initial tool for education, demonstration, and testing of leaf color analysis logic. This application separates the contribution of the software from claims regarding plant physiology, thereby making the scope of the research clearer and more measurable. This approach is relevant for situations where researchers do not yet have a chlorophyll meter, SPAD meter, or real leaf dataset, but still wish to build the foundation for a computationally testable image analysis system.

A limitation of this study's novelty is that the classifications of "healthy," "less healthy," and "unhealthy" are still visual-simulatory in nature. Hue values cannot yet be used for actual plant health diagnosis without physiological validation. Additionally, the implementation in Visual Basic 6.0 is legacy; therefore, further research is recommended to migrate the algorithm to Python, C#, or web-based applications, as well as to incorporate validation using real leaf images, controlled lighting conditions, and additional features such as Saturation, Value, texture, or simple machine learning models.

V. CONCLUSION

This study produced a Visual Basic 6.0-based HMI application prototype to support the simulated analysis of leaf greenness using the Hue feature in the HSV color space. The application is capable of loading or capturing images, displaying images, reading RGB values, converting RGB to HSV, calculating Hue, Saturation, and Value, and assigning color categories based on simulated rules.

Black-box testing showed that all the application's main functions operated as designed with a 100% success rate in the tested scenarios. Algorithmic verification demonstrated that the classification output followed the established rules based on Hue and Value values. However, the results of this study only demonstrate the application's functional and computational feasibility, not the physiological validation of the plants.

Further research is needed to incorporate real leaf images, lighting controls, camera variations, and reference data such as SPAD, chlorophyll, leaf nitrogen, or expert assessments. Additionally, the application could be redeveloped using a more modern platform and combined with features such as Saturation, Value, texture, ExG, NGRDI, G/R ratio, or simple machine learning methods.

ACKNOWLEDGMENT

Thanks to the entire academic community of the Doctoral Program in Agro-Industrial Technology, Faculty of Agro-Industrial Technology, Padjadjaran University, Sumedang, West Java, Indonesia, as well as to the Research Center for Smart Mechatronics and Telecommunications, National Research and Innovation Agency of the Republic of Indonesia, Bandung, Indonesia, who have assisted in the publication of this article. We hope this article will continue to be cited and prove useful to related academic disciplines.

Abstract*—Large-scale Flutter applications can accumulate direct inter-module dependencies, inconsistent responsibility boundaries, and inflexible data-access implementations as their functionality grows. Conventional scaffolding approaches primarily automate project structures and repetitive code, while architectural relationships commonly remain dependent on developer-level implementation decisions. This study proposes an architecture-aware Flutter code generation framework that transforms JavaScript Object Notation (JSON)-based application specifications into modular source code while systematically applying Clean Architecture, Mediator, and Strategy rules. The main contribution lies not in combining these established architectural concepts, but in encoding their architectural roles as repeatable specification-to-code transformation rules. The framework was evaluated using three application specifications containing one, two, and eight functional modules. All three applications were successfully generated, executed, and built into installable Android APKs. In the evaluated Login and Register interaction, two direct cross-module relationships observed in the legacy architecture were replaced by mediator-based communication, resulting in no direct Login and Register reference in the generated structure. The generated architecture also represented REST API and SQLite data providers through a common Strategy-based abstraction. These findings demonstrate operational feasibility and provide structural evidence that the intended architectural rules were incorporated into the evaluated generated artifacts. However, the evaluation is limited to the supported JSON schema, predefined generation templates, three application specifications, and the evaluated architectural relationships; therefore, the results should not be interpreted as general evidence of long-term maintainability, scalability, or superiority over other Flutter code generators.

Keywords*—Architecture-aware code generation; specification-driven development; flutter; clean architecture; mediator pattern; strategy pattern; software modularity

I. Introduction

Flutter has emerged as a widely adopted framework for cross-platform mobile application development because it enables applications for multiple platforms to be developed from a shared codebase while supporting efficient development processes and near-native performance [1]. However, as mobile applications grow in functional scope and architectural complexity, maintaining a consistent source-code structure becomes increasingly challenging. Large-scale applications may accumulate direct dependencies among functional modules, unclear responsibility boundaries, and dependency-related problems that increase the difficulty of software maintenance and evolution [2], [3].

Clean Architecture addresses these challenges by separating software responsibilities into distinct layers and directing dependencies toward stable abstractions [4]. Previous studies have shown that its application can improve responsibility separation, source-code organization, and maintainability in mobile software projects [5], [6]. Nevertheless, Clean Architecture primarily defines responsibility boundaries and dependency directions. It does not by itself prescribe a uniform mechanism for coordinating communication among functional modules or for representing interchangeable operational behaviors, such as alternative data-access mechanisms.

Behavioral design patterns provide complementary mechanisms for addressing these concerns. The Mediator pattern centralizes communication among participating components and reduces the need for direct references between them [7]. Its implementation in software systems has demonstrated how component interactions can be coordinated through an intermediary rather than through direct object-to-object dependencies [8]. The Strategy pattern encapsulates alternative algorithms or behaviors behind a common interface, allowing a concrete implementation to be selected or replaced without modifying its client [9]. In a modular Flutter application, these patterns can support controlled inter-module communication and flexible selection of data providers, including REST application programming interface (API) and SQLite implementations.

Existing Flutter studies have generally applied Clean Architecture manually within application-specific projects. For example, Clean Architecture has been implemented in a Flutter-based tourism application by manually defining the presentation, domain, and data structures required by the application [10].

Related software-engineering research has also emphasized that reducing dependencies among software components is

*Corresponding author.

important for architectural scalability and long-term system evolution [11], while separation of concerns contributes to the management of software complexity [12]. A reusable Flutter Clean Architecture package has additionally been proposed to provide predefined architectural components and assist developers in separating business logic from platform-specific implementation [13].

Although these approaches support architectural adoption, they still require developers to define functional modules, configure their relationships, implement inter-module communication, select data-access mechanisms, and maintain architectural consistency at the source-code level. Reusable packages and manually implemented architectures can reduce initial development effort, but they do not necessarily ensure that the same architectural constraints are applied consistently across all modules and application versions. Similarly, conventional scaffolding tools may generate folders, classes, and repetitive source-code artifacts without systematically enforcing the relationships among the generated components.

Within the literature reviewed in this study, limited attention has been given to transforming declarative Flutter application specifications into multi-module applications while systematically enforcing responsibility separation, mediator-based inter-module communication, and strategy-based data-provider variation during source-code generation. The research gap addressed in this study is therefore not the absence of Clean Architecture, Mediator, or Strategy as individual software-engineering concepts, since these concepts are already well established. Rather, the unresolved issue concerns their systematic enforcement as part of an automated specification-to-code generation process. Without such enforcement, architectural conformance remains dependent on developer expertise and local implementation decisions, potentially resulting in inconsistent dependency structures and architectural drift.

To address this gap, this study proposes an architecture-aware Flutter code generation framework that receives application specifications in JavaScript Object Notation (JSON) format and transforms them into modular Flutter source code. The JSON input serves as a blueprint that defines application-level properties, pages, routes, functional modules, and selected data providers. During generation, the framework applies Clean Architecture rules to organize software responsibilities, Mediator rules to coordinate communication among functional modules, and Strategy rules to represent REST API and SQLite data providers through interchangeable abstractions.

The principal novelty of the proposed framework does not lie merely in combining Clean Architecture with the Mediator and Strategy patterns. Its scientific contribution lies in encoding these architectural decisions as repeatable specification-to-code generation rules. Consequently, responsibility boundaries, communication mechanisms, and data-provider abstractions are established during source-code generation rather than being left entirely to post-generation manual implementation. This mechanism is intended to produce consistent architectural structures across modules with different functional responsibilities.

This study makes three main contributions. First, it defines a JSON-based specification-to-architecture mapping that transforms application properties, pages, routes, functional modules, and data-provider configurations into organized Flutter source-code artifacts. Second, it implements an automated generation mechanism that systematically applies Clean Architecture boundaries, mediator-based inter-module communication, and strategy-based data-provider variation during source-code generation. Third, it provides an empirical feasibility and structural evaluation using three application specifications with increasing modular complexity, including operational generation and build observations, a legacy–generated architectural comparison, and inspection of the generated Mediator and Strategy structures.

The evaluation examines whether the framework can successfully generate, execute, and build Flutter applications from the tested JSON specifications. Structural architectural characteristics are assessed by comparing the available legacy and generated application structures, examining direct functional-module relationships, and inspecting whether the generated source structure incorporates the intended Mediator and Strategy mechanisms. The results are interpreted as evidence of operational feasibility and architectural conformance within the evaluated scenarios. They are not considered complete proof of long-term maintainability, scalability, or testability because these broader quality attributes require larger application samples, repeated experiments, additional software-quality measurements, and longitudinal maintenance evaluation.

The remainder of this study is organized as follows. Section II critically reviews previous studies on Clean Architecture, behavioral design patterns, Flutter architectural approaches, code generation, and software-quality evaluation. Section III describes the proposed framework, JSON specification, architectural generation rules, experimental scenarios, and evaluation procedure. Section IV presents and discusses the operational and structural evaluation results. Section V discusses the threats to validity and limitations of the study. Finally, Section VI presents the conclusions and directions for future research.

II. Related Work

Clean Architecture has been applied in mobile software development to improve separation of concerns and control dependency directions. Rachovski et al. [4] used Clean Architecture principles to organize the design and implementation of a mobile platform, while Santiago-Salazar and Rico-Bautista [5] examined its impact on the performance and maintainability of native Android applications. In the Flutter context, Sinatria et al. [6] implemented Clean Architecture by separating presentation, domain, and data responsibilities. These studies indicate that layered architectural separation can clarify responsibility boundaries and improve source-code organization. However, the architectural structures in these studies were implemented manually within individual application projects, meaning that architectural consistency remained dependent on developer knowledge and implementation decisions.

Behavioral design patterns provide complementary mechanisms for managing software interactions and behavioral variation. The Mediator pattern centralizes communication among participating components, thereby reducing the need for direct references between them [7]. Petrova and Varbanov [8] demonstrated mediator-based communication and command handling using the MediatR library in a .NET environment. Meanwhile, the Strategy pattern encapsulates alternative algorithms or behaviors behind a common interface, allowing an implementation to be selected or replaced without modifying its client [9]. Although these studies establish the architectural roles of Mediator and Strategy, the patterns are generally applied manually at the source-code level. Consequently, their implementation may vary among modules, developers, and application versions.

Wijayanto and Sejati [10] applied Clean Architecture to a Flutter-based mobile tourism application and reported that the separation of presentation, domain, and data responsibilities supported application modularity and development. Nevertheless, the architectural components and their relationships were manually defined for the specific application rather than generated from a declarative specification. In a broader software-architecture context, Aljaloud and Razzaq [11] demonstrated the importance of reducing dependencies when restructuring monolithic software systems, while Idate et al. [12] emphasized separation of concerns as a mechanism for managing software complexity. These studies reinforce the importance of modularity and dependency management but do not provide an automated mechanism for generating modular Flutter applications.

A more directly relevant reusable solution was introduced by Boukhary and Colmenares [13] through the Flutter Clean Architecture Package. The package provides reusable architectural components that help developers separate business logic from platform-specific implementation. This approach reduces the effort required to establish a Clean Architecture structure in Flutter projects. However, a reusable architectural package differs from an architecture-aware code generator. Developers must still define the functional modules, configure dependencies, implement communication among modules, and determine how alternative data providers are integrated. Therefore, the package supports architectural implementation but does not automatically transform an application specification into a complete multi-module Flutter project with generated Mediator and Strategy structures.

Stirgwolt et al. [14] demonstrated that modular architectures can support system evolution by controlling relationships among components. Sangwan et al. [15] further emphasized that architectural dependency analysis is necessary because uncontrolled dependencies may increase change propagation and complicate software evolution. Sun et al. [16] investigated the relationship between dependency injection and software maintainability, demonstrating the relevance of dependency management to software-quality assessment.

Recent model-driven software-engineering studies provide a broader perspective on systematic and architecture-aware software generation. Lano et al. [17] proposed an agile model-driven re-engineering approach that uses software abstraction, semantic models, transformation, refactoring, and rearchitecting to support legacy-system modernization and platform migration. Their evaluation included practical re-engineering cases involving legacy systems and comparison of program-translation effectiveness, demonstrating how explicit model-driven transformations can support automated restructuring and target-code production.

Jiménez-Navajas et al. [18] proposed a model-to-text code-generation technique in which extended Unified Modeling Language (UML) design models are transformed into executable source code. Their approach uses explicit Model-to-Text transformations to generate Python and Qiskit code for classical-quantum systems and was evaluated through a multi-case study involving seven software systems. Although the target domain differs from Flutter mobile applications, the study provides a relevant example of specification-driven generation in which transformation rules and generated artifacts are explicitly defined and empirically evaluated.

Recent studies published in applied computer-science venues provide additional perspectives relevant to the present work. Tiali et al. [19] employed a model-driven engineering approach in which explicit transformation rules systematically map business-process representations into generated executable smart-contract artifacts. Although their source and target technologies differ from the present study, their work illustrates the importance of making transformation rules explicit when automated generation is claimed. In the mobile-software context, Yataco et al. [20] demonstrated the practical use of Clean Architecture in an implemented mobile system, showing the continuing relevance of responsibility separation and modular architectural organization in application development. From a software-quality perspective, Abufakher [21] empirically investigated GoF design patterns using multiple object-oriented quality metrics, illustrating the importance of explicitly defined measurement procedures when quantitative structural metrics are reported.

These studies strengthen the methodological positioning of the present work because they demonstrate that model- or specification-driven software generation can encode explicit transformation rules rather than relying exclusively on manual implementation. However, none of these studies addresses the generation of modular Flutter applications in which Clean Architecture organization, mediator-based inter-module communication, and strategy-based data-provider variation are jointly incorporated into the generated source structure.

Collectively, these studies demonstrate that architectural quality can be examined from multiple structural perspectives, including cohesion, coupling, modular organization, and dependency relationships. They also indicate that individual static metrics capture only selected characteristics of a software architecture and should not be interpreted as complete measures of long-term maintainability, scalability, testability, or developer effort. Accordingly, the present study focuses its empirical structural evaluation on directly observable architectural relationships in the evaluated artifacts, particularly direct functional-module dependencies and the generated Mediator and Strategy structures.

Table I compares representative related approaches according to their target platforms, input mechanisms, architectural support, levels of automation, evaluation methods, and remaining limitations. The comparison distinguishes manually implemented Clean Architecture applications, reusable architecture packages, model-driven generation approaches, and the architecture-aware Flutter code generation framework proposed in this study.

As shown in Table I, existing Flutter studies mainly apply Clean Architecture manually or provide reusable architectural components whose final configuration remains developer-controlled. In contrast, recent model-driven approaches [17], [18] demonstrate that explicit software representations can be transformed systematically into generated artifacts. The proposed framework combines these two directions by using a declarative JSON specification to generate Flutter source code while incorporating predefined Clean Architecture organization, Mediator-based inter-module communication, and Strategy-based data-provider variation.

Nevertheless, Table I should be interpreted as a capability-level comparison rather than a direct performance benchmark. The reviewed studies differ in platform, input representation, transformation objectives, generated technologies, and evaluation procedures. Therefore, the empirical evaluation in this study uses the available legacy application as an internal structural baseline, while a controlled comparison with functionally equivalent external Flutter generators remains future work.

TABLE I. COMPARISON OF RELATED ARCHITECTURAL APPROACHES

Study	Platform / Input	Architectural Support	Automation Level	Evaluation	Remaining Limitation
Wijayanto and Sejati [10]	Flutter; manually implemented requirements	Clean Architecture for modular mobile	Manual application-specific implementation	Functional application case study	Not generated from declarative specification
Boukhary and Colmenares [13]	Flutter; reusable package and developer configuration	Reusable Clean Architecture components	Package-assisted; assembly remains developer-controlled	Package demonstration/application implementation	No complete specification-driven multi-module generation
Lano et al. [17]	Legacy software and semantic models	Refactoring, restructuring, rearchitecting, migration	Automated/model-driven transformation	Real-world legacy cases and translation evaluation	Different target problem/platform; no Flutter Mediator/Strategy generation
Jiménez-Navajas et al. [18]	Extended UML models	Model-driven source-code generation	Automated Model-to-Text transformation	Seven-system multi-case study	Different target domain/output technology; no Flutter architecture-pattern enforcement
Proposed framework	Flutter; JSON application specifications	Clean Architecture organization, Mediator communication, Strategy data-provider variation	Automated specification-to-code generation	One-, two-, and eight-module scenarios; execution/build validation; structural evaluation	Limited to supported JSON schema, templates, modules, and evaluated scenarios

III. METHODOLOGY

A. Framework Overview and Architecture

This study evaluates a Clean Code Generator developed as part of the CleanApp environment. The generator receives an application specification in JSON format and produces Flutter source-code artifacts using predefined generation templates. The JSON configuration describes the structure and functional elements of the target application, while the generation mechanism incorporates architectural structures based on Clean Architecture, Mediator, and Strategy. The resulting Flutter project is subsequently executed, built into an Android application package (APK), and inspected through operational and structural architectural evaluation.

B. JSON-Based Application Specification

The Clean Code Generator receives its input as a JSON configuration produced by the CleanApp Builder. The configuration describes the application structure to be generated, including application-level information, page definitions, navigation routes, data-provider configurations, optional features, and application branding information. The JSON specification therefore serves as a declarative representation of the target application, while the generator translates the supplied configuration into the corresponding Flutter source-code structure.

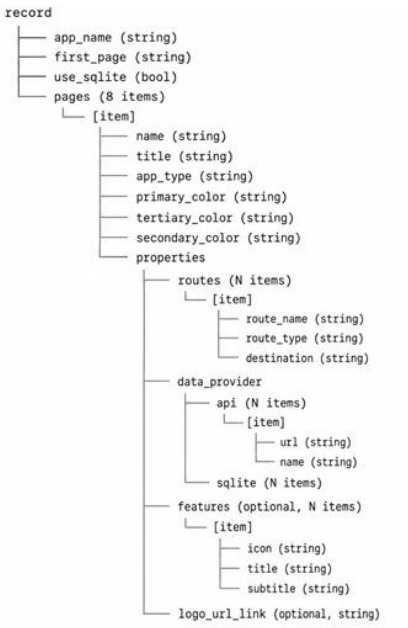

Fig. 1. Structure of the JSON application.

As shown in Fig. 1, the specification contains three application-level elements: app_name, first_page, and use_sqlite. The pages collection contains the definitions of the

functional pages included in the generated application. Each page contains descriptive attributes, including its name, title, application type, and interface colors. The properties element contains the configuration required to determine navigation, data access, optional features, and application branding.

Navigation is represented through the routes collection, in which each route contains route_name, route_type, and destination. Data-access requirements are represented by the data_provider element, which can contain API- and SQLite-based configurations. An API entry contains a url and name, while the SQLite configuration can contain multiple entries depending on the application specification.

The high-complexity configuration can additionally contain optional features, consisting of icon, title, and subtitle, as well as an optional logo_url_link.

TABLE II. JSON SPECIFICATION CHARACTERISTICS OF THE EXPERIMENTAL SCENARIOS

Configuration element	Low Complexity	Medium Complexity	High Complexity
pages	1 item	2 items	8 items
routes	2 items	N items	N items
data_provider.api	0 items	0 items	N items
data_provider.sqlite	0 items	0 items	N items
features	Not shown	Not shown	Optional, N items
logo_url_link	Present	Not shown in displayed schema	Optional

Note: N denotes a variable number of items in the displayed JSON schema rather than a fixed experimental count.

The number of elements varies according to the application scenario. Therefore, the JSON specification does not directly encode a fixed application implementation; instead, it defines the application elements that must be interpreted by the generator. The generator subsequently applies its predefined architectural rules and source-code templates to produce the corresponding Flutter project.

Table II highlights the differences among the JSON structures used in the three experimental scenarios. The low-complexity configuration contains a single page and two navigation routes, whereas the medium-complexity configuration contains two pages and supports a variable number of routes. In both displayed configurations, the API and SQLite provider collections contain no items. The high-complexity specification extends this structure to eight pages and supports multiple routes, API and SQLite entries, optional feature definitions, and an optional logo URL. Thus, experimental scenarios increase not only in the number of generated functional components but also in the richness of the configuration processed by the generator.

C. Architecture-Aware Code Generation Mechanism

The proposed framework transforms the JSON specification into Flutter source-code artifacts using predefined code templates and architectural rules. Clean Architecture provides the structural organization of the generated application, while the Mediator and Strategy patterns define specific relationships among generated components. The Mediator mechanism is used to coordinate communication among functional modules without requiring direct module-to-module references, whereas the Strategy mechanism is used to organize alternative data-access implementations behind a common abstraction. Thus, the generator does not merely produce project folders and repetitive source code; it also embeds predefined architectural relationships into the generated project.

In the generated architecture, each functional module contains a controller that acts as the principal coordination point for the corresponding module. Interactions that involve other functional modules are routed through the generated mediator structure, while data-access alternatives such as REST API and SQLite are represented through Strategy-based components. This mechanism allows the same architectural conventions to be repeatedly applied to different application specifications and functional modules.

The architecture-aware generation mechanism can be summarized as a set of specification-to-code transformation rules. These rules determine how application elements and architectural conditions are translated into generated source-code structures. Table III summarizes the principal rules implemented by the framework and the architectural structures produced by each rule.

TABLE III. SPECIFICATION-TO-CODE ARCHITECTURAL GENERATION RULES

Specification or Architectural Condition	Generation Rule	Generated Structure / Architectural Effect
Functional page or module definition	Generate the corresponding functional-module source structure, including its controller, using the predefined architectural templates	Module responsibilities are organized according to the predefined Clean Architecture structure
Interaction involving different functional modules	Route cross-module communication through the generated Mediator component rather than generating direct module-to-module references	Mediator-based inter-module coordination
REST API data-provider configuration	Generate the API-specific data-provider implementation behind the common data-provider abstraction	Strategy-based representation of REST API access
SQLite data-provider configuration	Generate the SQLite-specific data-provider implementation behind the same data-provider abstraction	Strategy-based representation of SQLite access

In this study, architecture-aware generation refers to a code-generation process in which predefined architectural rules are applied during the transformation from the JSON specification to source-code artifacts, rather than generating only syntactic scaffolding. Architectural enforcement refers to the generation-time instantiation of these selected rules in the produced source structure, so that the corresponding architectural decisions are not left entirely to post-generation developer implementation. Architectural conformance is operationally defined as the observable agreement between the generated artifacts and the specific architectural rules evaluated in this study, namely the predefined module organization, Mediator-based routing of the evaluated cross-module interaction, and Strategy-based representation of REST API

and SQLite data providers. This definition is limited to the inspected architectural relationships and does not constitute formal verification of all Clean Architecture dependency constraints.

These rules distinguish the proposed framework from conventional scaffolding that primarily generates repetitive project artifacts. In the proposed approach, the generator also determines selected architectural relationships during source-code generation. Consequently, module organization, cross-module communication, and data-provider variation are instantiated according to predefined architectural rules rather than being left entirely to post-generation manual implementation.

D. Code Generation Workflow

Fig. 2 summarizes the specification-to-code generation and validation workflow. The code-generation process begins when the Clean Code Generator receives a JSON configuration produced by the CleanApp Builder.

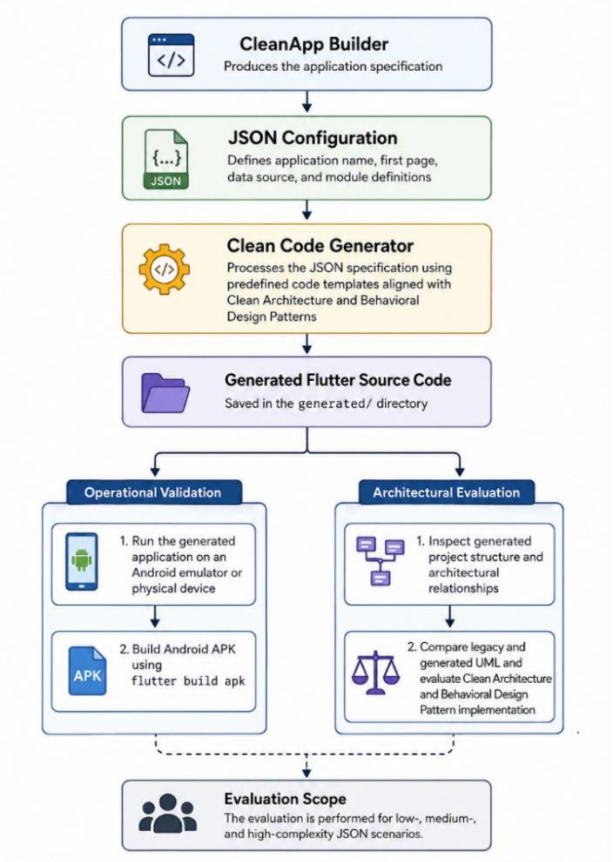

Fig. 2. Workflow of the specification-to-code generation and validation process.

The framework first reads the application-level configuration and identifies the pages, navigation routes, functional modules, and data-provider requirements defined in the specification. The corresponding source-code templates are then selected and used to generate the required Flutter project artifacts. During this process, the predefined architectural structures for Clean Architecture, Mediator-based communication, and Strategy-based data access are incorporated into the generated source code.

After generation, the resulting files are organized into a standalone Flutter project. The generated project is subsequently executed in the development environment or on an Android device to verify that the application can run successfully. Finally, the project is built into an Android APK and its source-code structure is inspected for architectural evaluation. This workflow therefore covers the complete process from declarative application specification to generated, executable, and structurally evaluated Flutter application.

E. Experimental Design and Environment

The framework was evaluated using three JSON-based application specifications representing increasing levels of functional complexity. The low-complexity scenario contained one functional module implementing a registration form. The medium-complexity scenario contained two functional modules, Setting and User. The high-complexity scenario incorporated all functional modules available in the evaluated framework configuration. These three scenarios were selected to examine whether the same generation mechanism could process application specifications with different numbers of functional components while preserving the intended project structure.

Table IV summarizes the evaluated scenarios, including their relative configuration scale, number of functional modules, and functional scope.

TABLE IV. EXPERIMENTAL SCENARIOS

Scenario	Scenario Scale	Modules	Functional Scope
S1	Low	1	Registration
S2	Medium	2	Setting and User
S3	High	8	Login, E-commerce List, E-commerce Square, Note, Onboarding, Register, Settings, and User

The experiments were conducted from August 2024 to June 2025. The primary development machine was equipped with an 11th-generation Intel Core i5 processor, 16 GB of RAM, and a 512 GB SSD. The software environment consisted of Flutter Software Development Kit (SDK) 3.24.5, Dart SDK 3.5.4, Android Studio Jellyfish 2023.3.1, and Visual Studio Code. The generated applications were additionally validated using two Android devices: one device equipped with an Exynos 9611 chipset, 4 GB of RAM, and Android 10, and another equipped with a MediaTek Dimensity 700 chipset, 8 GB of RAM, and Android 13.

In this experiment, the terms low, medium, and high complexity are used as descriptive scenario labels reflecting the increasing number of functional modules and the relative richness of the corresponding JSON specifications. They should not be interpreted as formal measurements of software complexity, dependency density, interaction complexity, generated-code volume, architectural depth, or cyclomatic complexity. The three scenarios were selected to examine whether the same generation mechanism could process

specifications with different numbers of functional components while preserving the intended project structure.

F. Evaluation Procedure

The evaluation consisted of two complementary stages: operational validation and structural architectural evaluation. Operational validation examined whether each JSON specification could be successfully processed into Flutter source code, whether the generated project contained the expected directory and source-code structure, whether the application could be executed on the experimental environment, and whether an Android APK could be successfully built. Generation time, APK build time, and APK size were recorded as descriptive operational characteristics.

Structural architectural evaluation examined whether the generated source code exhibited the intended architectural relationships. The generated application structure was represented using UML class diagrams and compared with the available legacy application architecture. The comparison focused on direct relationships between functional modules and on whether the generated application routed cross-module communication through the Mediator component. The generated Strategy structure was also inspected to verify the representation of REST API and SQLite data-provider implementations through a common abstraction.

For the structural comparison, a direct functional-module dependency was counted when a class belonging to one functional module directly referenced a class belonging to another functional module without an intermediary architectural abstraction. Dependencies routed through the generated Mediator abstraction were treated as mediated relationships and were therefore not counted as direct functional-module dependencies. The comparison was restricted to the evaluated Login–Register interaction for which corresponding structural evidence was available in both the legacy and generated architectures.

Accordingly, the structural evaluation focuses on architectural relationships that can be directly inspected from the available generated and legacy artifacts. The evaluation does not attempt to provide a comprehensive quantitative assessment of software maintainability or overall architectural quality.

IV. Results and Discussion

A. Framework Validation

The operational validation was conducted using three application-generation scenarios with different levels of functional complexity. The scenarios consisted of low-complexity applications with a single module, medium-complexity applications with two modules, and high-complexity applications containing all available functional modules. For each scenario, the framework was required to successfully generate source code and produce a buildable Flutter application.

Operational success in this evaluation indicates that the generated projects could be produced, executed, and built successfully under the tested configurations. However, successful execution and APK construction do not by themselves establish functional correctness with respect to every behavioral requirement represented in the JSON specifications. A systematic requirements-to-behavior verification was outside the scope of the present evaluation.

TABLE V. Framework Validation

Complexity	Modules	Code Generation	Application Execution	APK Build
Low	1	Successful	Successful	Successful
Medium	2	Successful	Successful	Successful
High	8	Successful	Successful	Successful

Table V summarizes the operational validation results. All three evaluated specifications were successfully generated, executed, and built into Android APKs. Because each scenario was evaluated once, these observations demonstrate operational feasibility within the tested configurations rather than a generalized reliability rate.

B. Structural Comparison of Legacy and Generated Architectures

The legacy and generated application structures were compared to examine differences in direct functional-module relationships after the introduction of mediator-based coordination. The comparison focuses on the evaluated Login–Register interaction, for which corresponding structural evidence is available in both architectures.

TABLE VI. Structural Comparison of the Evaluated Legacy and Generated Interaction

Structural Aspect	Legacy Architecture	Generated Architecture
Evaluated interaction	Login ↔ Register	Login ↔ Register through Mediator
Direct functional-module dependencies	2 directed relationships	0 direct relationships
Inter-module coordination	Direct cross-module references	Mediator-based coordination
Architectural interpretation	Modules directly reference one another	Direct references replaced by mediated communication

Table VI summarizes the structural comparison of the evaluated Login–Register interaction. In the legacy architecture, two directed cross-module relationships were observed between the corresponding components. In the generated architecture, no direct Login–Register relationship was observed because the interaction is routed through the Mediator component. Thus, the direct functional-module dependency count decreases from two to zero for this evaluated interaction. This result provides structural evidence of reduced direct coupling, although the generated modules remain dependent on the Mediator abstraction.

TABLE VII. Operational Measurements

Complexity	Modules	Generation Time (ms)	Build Time (s)	APK Size (MB)
Low	1	1,311	38.3	49.0
Medium	2	1,351	302.5	49.8
High	8	1,474	249.7	65.8

Table VII presents the descriptive operational measurements of the three evaluated specifications. Generation time increased from 1,311 ms for the single-module specification to 1,474 ms for the eight-module specification. APK size increased from 49.0 MB to 65.8 MB across the same configurations. In contrast, build time did not exhibit a monotonic relationship with the number of modules, with recorded values of 38.3 s, 302.5 s, and 249.7 s. Because each specification was evaluated once, these measurements are reported descriptively and are not interpreted as statistically validated evidence of runtime or build scalability.

The non-monotonic build-time pattern cannot be attributed to configuration scale from the present measurements alone. Potential contributing factors may include build-system state, dependency resolution, incremental-build or caching conditions, and background execution variability. Because these factors were not independently controlled or recorded during the experiment, the observed differences are treated as descriptive tooling and execution variability rather than evidence of a systematic relationship between module count and build time. Repeated measurements under controlled build conditions are required to distinguish these effects.

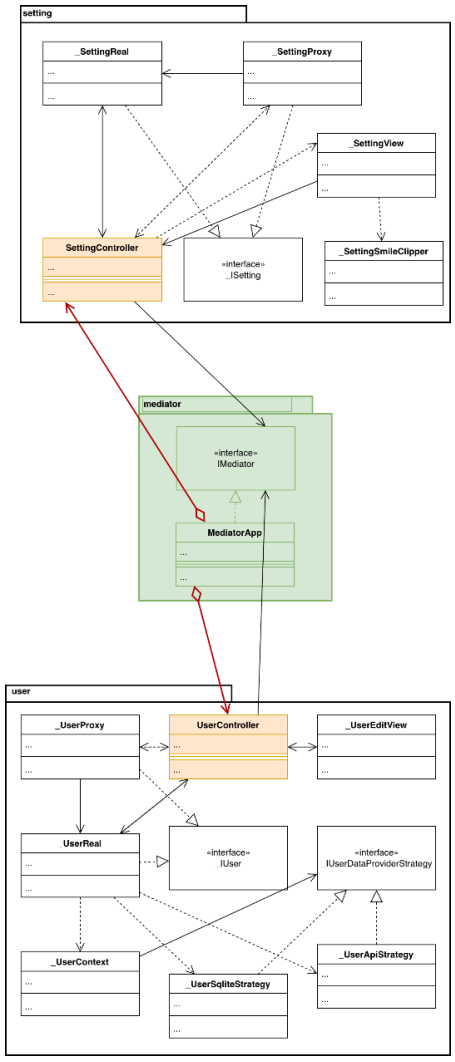

Fig. 3. UML diagram illustrating the mediator pattern implementation.

C. Implementation of Mediator Pattern

Fig. 3 illustrates the Mediator structure generated by the framework. In the evaluated generated architecture, the inter-module interaction represented in the structural comparison is coordinated through the Mediator component rather than through the direct Login–Register references observed in the legacy architecture.

The generated Mediator structure routes the evaluated inter-module interactions through a common coordination mechanism rather than through direct cross-module references. This organization reduces explicit relationships between the participating functional modules and may limit change propagation caused by direct references. However, the actual maintenance effort required to modify or extend the generated modules was not measured in the present study.

D. Implementation of Strategy Pattern

Fig. 4 illustrates the Strategy structure generated by the framework. The structure represents REST API and SQLite implementations through a common data-provider abstraction.

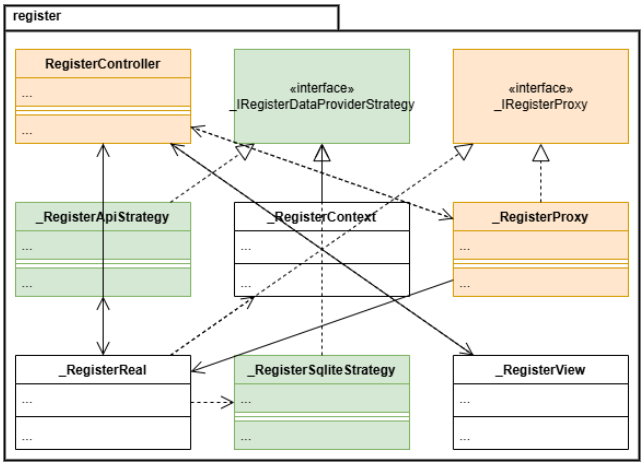

Fig. 4. UML diagram illustrating the strategy pattern implementation.

This organization separates provider-specific behavior from controller-facing logic and structurally supports provider substitution or extension. However, the experiment did not include a controlled change task measuring the files, source-code modifications, or developer effort required to introduce an additional provider. Therefore, the result is interpreted as structural support for extensibility rather than quantitative evidence of reduced maintenance effort.

E. Discussion

The evaluation provides complementary evidence concerning operational feasibility and architectural structure. Operationally, the proposed framework successfully generated, executed, and built Flutter applications from all three tested JSON specifications, covering one-, two-, and eight-module configurations. These results indicate that the generation mechanism can operate across the evaluated levels of functional complexity. Nevertheless, the limited number of specifications means that the findings demonstrate feasibility within the tested configuration space rather than general reliability across arbitrary Flutter applications.

The comparison between the legacy and generated architectures provides additional evidence regarding inter-module dependency management. In the evaluated Login–Register interaction, the legacy architecture contains two direct cross-module relationships, whereas the generated architecture replaces these direct relationships with communication through the Mediator component. Accordingly, the direct functional-module dependency count decreases from two to zero for this evaluated interaction. This result supports the intended role of the Mediator generation rule in reducing direct relationships among functional modules. However, the mediator remains an architectural dependency and may itself become a coordination point as the number and complexity of module interactions increase.

The Strategy implementation provides complementary structural support for variation in data-access behavior. REST API and SQLite implementations are represented through a common provider abstraction, allowing provider-specific behavior to remain separated from controller-facing logic. This demonstrates that the generator can systematically encode alternative data-access mechanisms within the generated architecture. Nevertheless, no controlled change-impact experiment was performed to quantify the effort required to introduce an additional provider. Therefore, the current evidence supports architectural extensibility at the structural level but does not establish a quantitative reduction in maintenance effort.

The results should also be interpreted within the limitations of the selected evaluation evidence. Direct functional-module relationships and UML-based architectural inspection capture observable aspects of dependency organization and generated structure, but they do not represent all dimensions of software quality. Maintainability, scalability, and testability are multidimensional properties that may also depend on source-code complexity, test coverage, runtime behavior, developer comprehension, defect history, and long-term evolution. Accordingly, the present study limits its conclusions to the architectural relationships and operational behavior directly supported by the evaluated artifacts.

A direct empirical benchmark against external Flutter code generators was not conducted because the reviewed approaches differ in functional scope, input representation, architectural objectives, and availability of comparable implementations. For this reason, existing approaches are compared at the capability level in the Related Work section, while the empirical architectural comparison uses the available legacy application as an internal baseline. A controlled benchmark using functionally equivalent application specifications and reproducible external generators remains an important direction for future work.

Overall, the findings indicate that the proposed architecture-aware generation approach can transform the evaluated JSON specifications into executable Flutter applications while applying predefined rules for module organization, mediator-based communication, and strategy-based data access. The evidence supports architectural conformance and controlled direct coupling in the evaluated cases, but broader claims regarding long-term maintainability, large-scale scalability, and developer productivity require additional longitudinal and comparative experiments.

V. Threats to Validity

The study does not report comprehensive quantitative source-code quality or architectural metrics, such as coupling measures, dependency-violation counts, cyclomatic complexity, generated lines of code, or class-level structural metrics. Accordingly, the reported structural evidence should be interpreted as targeted architectural inspection rather than as a comprehensive quantitative assessment of generated-code quality. Future evaluations should incorporate reproducibly defined source-code and architecture metrics alongside structural inspection. This study has several limitations that should be considered when interpreting the results.

A. Internal Validity

The generated applications depend on predefined templates and architectural generation rules. Consequently, defects or biases in these templates may influence the resulting architectural structures. To reduce this threat, the same generator, JSON configuration mechanism, software environment, and evaluation procedure were applied to all three experimental scenarios. The generated outputs and UML structures were also inspected to verify that the intended Mediator and Strategy relationships were present.

B. Construct Validity

The structural evaluation focuses on directly observable architectural relationships, including direct functional-module dependencies and the representation of Mediator- and Strategy-based structures. These observations capture selected aspects of architectural organization but do not directly measure broader software-quality attributes such as maintainability, scalability, testability, developer comprehension, or maintenance cost. Likewise, generation time, build time, and APK size are operational characteristics rather than direct measures of these quality attributes. Therefore, the findings are interpreted as evidence of operational feasibility and structural architectural conformance within the evaluated scenarios.

C. Conclusion Validity

The evaluation involved three application specifications, and each scenario was executed once. Consequently, the reported generation and build results are descriptive observations rather than statistical estimates of framework reliability or performance. No claim of statistical superiority over other code generators is made. The three specifications were selected to represent increasing functional complexity rather than to constitute a statistically representative sample of Flutter applications.

D. External Validity

The experiments were limited to Flutter applications generated from the supported JSON schema, predefined templates, and eight available functional modules. Applications requiring highly customized state management, platform-specific integrations, or architectural relationships outside the supported abstractions may require additional manual implementation. Therefore, the findings should be generalized

only to application structures that fall within the current framework configuration.

In practical terms, the current framework is most applicable to modular Flutter applications whose pages, routes, functional modules, and data-provider requirements can be represented by the supported JSON schema. Projects requiring highly customized architectural structures may require extensions to the schema or generation templates. Therefore, industrial adoption should also consider template customization and integration with manually maintained source code.

VI. Conclusion

This study proposed an architecture-aware Flutter code generation framework that transforms JSON-based application specifications into modular source code while systematically applying Clean Architecture, Mediator, and Strategy rules. The primary contribution is not the isolated use of these established architectural concepts, but their encoding as repeatable specification-to-code generation rules that are instantiated in the evaluated generated application structures.

The framework successfully generated, executed, and built all three evaluated application specifications containing one, two, and eight functional modules. In the structural comparison, the two direct Login–Register relationships observed in the legacy architecture were replaced by mediator-based communication in the generated architecture, resulting in no direct Login–Register relationship for the evaluated interaction. The generated Strategy structure also represented REST API and SQLite data providers through a common abstraction, demonstrating that the intended data-provider variation was incorporated into the generated architecture.

These findings should be interpreted within the scope of the experiment. The evaluation was limited to three predefined specifications, template-generated Flutter applications, selected architectural relationships, and single executions of each scenario. Therefore, the results do not constitute general proof of long-term maintainability, unlimited scalability, or superiority over other Flutter code generators.

Future work should evaluate larger industrial applications, perform repeated performance experiments, compare the framework with functionally equivalent and reproducible generators, conduct controlled maintenance and change-impact studies, and assess developer effort and comprehension. Additional work may also extend the JSON specification and generation templates to support further architectural and behavioral design patterns.

More broadly, architecture-aware code generation provides a practical direction for transforming architectural decisions from developer-dependent guidelines into explicit and repeatable software-construction rules.

A Unified Agent-Based Simulation Framework for Epidemic and Wildfire Propagation in Complex Adaptive Systems

Natasha Stojkovikj, Aleksandra Stojanova Ilievska, Limonka Koceva Lazarova, Daniel Eftimov, Irena Eftimova
Faculty of Computer Science, Goce Delcev University, Stip, North Macedonia

***Abstract*—Spreading phenomena in complex adaptive systems often exhibit similar dynamic characteristics despite originating from different application domains. This study investigates heterogeneous spreading processes using a common agent-based modeling methodology implemented in the AnyLogic simulation platform. Two representative models were developed: influenza transmission within a university population and wildfire propagation in a forest environment. Both models employ statechart-based agents, stochastic state transitions, and local interactions while preserving domain-specific characteristics. The influenza model incorporates mask usage, vaccination, and isolation as intervention strategies. Simulation results show that the investigated intervention scenarios reduced epidemic intensity compared with the baseline under the specific parameter settings considered, with peak infectious populations ranging from 44 to 70 individuals compared with 104 in the baseline scenario. The wildfire model investigates the influence of vegetation density, wind conditions, and burning duration, with burned trees ranging from 1 to 1,035 depending on environmental conditions. Comparative analysis demonstrated that both systems exhibit marked changes in propagation dynamics across the investigated scenarios, together with strong dependence on local interactions and stochastic processes. The successful application of a common agent-based modeling methodology across two distinct spreading phenomena highlights its consistency and transferability while supporting decision-making in public health and environmental risk management.**

***Keywords*—Agent-based modeling; AnyLogic; complex adaptive systems; influenza transmission; wildfire propagation**

I. Introduction

Many natural and social systems are characterized by processes that spread through interactions among neighboring entities. Examples include infectious diseases, wildfires, information diffusion, and cascading failures in infrastructure systems. Although these phenomena belong to different scientific domains, they often exhibit similar propagation patterns influenced by local interactions, stochastic effects, threshold behavior, and nonlinear dynamics. Understanding these processes is important for improving prevention strategies, supporting decision-making, and reducing potential societal, environmental, and economic impacts. Despite differences in their physical mechanisms, many spreading phenomena exhibit comparable emergent behaviors that can be investigated using similar agent-based modeling concepts.

Agent-based modeling (ABM) has been widely used for studying complex systems because it allows individual entities, their behavior, and interactions to be represented explicitly. In contrast to aggregate mathematical approaches, agent-based simulations enable researchers to investigate how relatively simple local rules may lead to complex system-level behavior. This capability has contributed to the increasing use of ABM in epidemiology, ecology, transportation systems, disaster management, and social sciences. In addition, modern simulation environments such as AnyLogic provide flexible mechanisms for implementing state-based agents, spatial interactions, and stochastic processes within a unified modeling framework. Such flexibility enables heterogeneous spreading phenomena to be investigated using a common modeling methodology, facilitating cross-domain comparisons while improving the transparency, interpretability, and reproducibility of simulation studies.

Seasonal influenza remains one of the most common infectious diseases worldwide and continues to place a considerable burden on healthcare systems and society. Educational institutions represent environments in which disease transmission can occur rapidly due to frequent interpersonal contacts, shared facilities, and high population densities. Investigating the dynamics of influenza outbreaks and evaluating the effects of protective measures are therefore important research topics in public health and epidemic modeling.

Wildfires represent another type of spreading phenomenon that has received substantial attention in recent years. Increasing temperatures, prolonged drought periods, and changing climatic conditions have contributed to more frequent and severe wildfire events in many regions of the world. Fire propagation depends on multiple factors, including vegetation density, wind conditions, burning duration, and local neighborhood interactions. Understanding how these factors influence wildfire dynamics is essential for improving prevention strategies, optimizing resource allocation, and supporting emergency response planning.

Most existing studies investigate epidemic transmission and wildfire propagation as separate research problems, primarily focusing on domain-specific models and applications. Consequently, relatively limited attention has been devoted to developing unified agent-based modeling frameworks that enable the systematic investigation of heterogeneous spreading phenomena using consistent modeling principles and comparable simulation structures. Although these phenomena share several fundamental propagation characteristics, including

local interactions, stochastic state transitions, and emergent behavior, their common modeling potential has received comparatively little attention. A cross-domain perspective may therefore provide a broader understanding of generic propagation mechanisms in complex adaptive systems while demonstrating the transferability of common agent-based modeling principles across different application domains.

Therefore, the objective of this study is to investigate whether different spreading phenomena can be consistently analyzed using a common agent-based modeling methodology implemented in the AnyLogic simulation environment. To achieve this objective, two agent-based models were developed. The first model represents influenza transmission within a higher education institution, while the second simulates wildfire propagation in a forest environment. Both models employ statechart-based agents, discrete spatial representations, and stochastic local interactions. Their comparative analysis enables the identification of common propagation characteristics while illustrating the applicability of agent-based simulation for studying heterogeneous spreading processes in complex adaptive systems.

The main contributions of this study are threefold. First, two comparable agent-based simulation models representing biological and environmental spreading phenomena are developed using a common statechart-based modeling methodology implemented in the AnyLogic platform. Second, the proposed models are comparatively evaluated under multiple intervention and environmental scenarios to investigate similarities and differences in propagation dynamics. Third, the study identifies common characteristics of spreading processes across heterogeneous complex adaptive systems, demonstrating the generalizability of agent-based simulation for cross-domain modeling of spreading phenomena.

The remainder of the study is organized as follows. Section II presents an overview of related studies in epidemic simulation, wildfire modeling, and agent-based methodologies. Section III introduces the theoretical concepts underlying the proposed models. Section IV describes the development and implementation of the influenza and wildfire simulations. Experimental results and comparative analyses are discussed in Section V, while Section VI summarizes the main findings and outlines potential directions for future research.

II. Related Work

Agent-based modeling (ABM) has become one of the most widely adopted approaches for studying complex adaptive systems characterized by heterogeneous entities, decentralized interactions, and emergent behavior. Unlike aggregate mathematical models, ABM explicitly represents individual agents, their behavioral rules, and interactions within a dynamic environment, allowing researchers to investigate how local decisions and stochastic processes collectively shape system-level dynamics. The applicability of agent-based techniques has been demonstrated in numerous scientific disciplines, including epidemiology, social sciences, transportation systems, ecology, and disaster management [1]–[4]. The development of multimethod simulation environments has additionally facilitated the implementation of ABM by enabling the integration of agent-based, discrete-event, and system dynamics paradigms within a common modeling framework [4].

The spread of infectious diseases has traditionally been investigated using compartmental epidemiological models. The classical SIR framework remains one of the most important theoretical foundations for epidemic modeling [5], while subsequent studies extended these concepts and demonstrated their usefulness for understanding disease dynamics and evaluating intervention strategies [6]. However, compartmental models generally assume homogeneous populations and often neglect heterogeneity in contact structures, mobility patterns, and individual behavior. To overcome these limitations, network-based and agent-based approaches have gained increasing attention [7]–[9].

Numerous studies have investigated influenza outbreaks and pandemic mitigation measures. Strategies for containing pandemic influenza at its source were investigated in [10], while targeted layered containment approaches were modeled in [11]. The role of herd immunity in infectious disease control was examined in [12]. School closure as a mitigation strategy was investigated in [13] and further evaluated in the context of the 2009 H1N1 pandemic in [14]. Factors affecting the controllability of infectious disease outbreaks were analyzed in [15], whereas a stochastic agent-based approach for epidemic simulation was developed in [16]. More recent research has expanded the methodological scope of epidemic modeling. An agent-based model incorporating non-pharmaceutical interventions and contact tracing was presented in [17]. A broader analysis of agent-based epidemic modeling approaches, applications, and future directions was provided in [18], while epidemic processes in complex networks were examined in [19].

Complex network theory has also played an important role in epidemic research. The influence of social network structures, connectivity patterns, and contact heterogeneity on disease transmission has been widely investigated [7], [20], [21]. These studies demonstrate that epidemic propagation is strongly influenced by local interactions among individuals as well as by the topology of the underlying contact network.

Wildfire propagation has been investigated through empirical, physical, and simulation-based approaches. Early studies demonstrated that simple local ignition mechanisms may generate self-organized critical behavior in forest-fire systems [22], [23]. Percolation theory has frequently been employed to explain the existence of critical vegetation density thresholds that significantly influence fire spread [24]. Cellular automata have also proven effective in modeling wildfire behavior, particularly when accounting for neighborhood interactions and environmental conditions [25]. More recent wildfire studies address different aspects of model realism. An efficient wildfire propagation approach using irregular grids was proposed in [26]. The effects of input-data variation and parameter adjustment were investigated in [27], while wildfire spread models addressing spotting phenomena were systematically reviewed in [28]. Together, these studies highlight complementary directions for improving spatial representation, parameterization, and the representation of complex fire-spread mechanisms. However, comparatively little attention has been devoted to investigating whether these modeling principles can

be generalized and consistently applied across different categories of spreading phenomena.

Although epidemic transmission and wildfire propagation are generally investigated within different scientific disciplines, both represent spreading phenomena governed by local interactions, stochastic state transitions, neighborhood effects, and nonlinear emergent dynamics. Consequently, both systems can be investigated using similar agent-based modeling concepts despite their fundamentally different physical mechanisms. Recent studies have additionally demonstrated the applicability of AnyLogic for modeling epidemic processes, educational environments, and other complex adaptive systems [29]–[32]. Nevertheless, these studies primarily focus on individual application domains rather than proposing a unified methodological framework for investigating heterogeneous spreading phenomena.

Building upon these observations, the present study adopts a common agent-based modeling methodology, implemented in the AnyLogic simulation environment, to investigate two different spreading phenomena. Rather than treating epidemic transmission and wildfire propagation as isolated case studies, the proposed approach explores their common propagation characteristics using comparable modeling principles, thereby providing a cross-domain perspective on the analysis of spreading dynamics in complex adaptive systems.

III. Theoretical Background

Agent-based modeling (ABM) is a bottom-up simulation approach in which autonomous entities interact within a predefined environment according to specific behavioral rules. In contrast to aggregate mathematical models, agent-based simulations describe the state and behavior of individual entities explicitly, making it possible to investigate how local interactions and stochastic events contribute to the emergence of system-level dynamics [1]–[4]. The ability to incorporate heterogeneous populations, spatial relationships, and adaptive behavior has led to the widespread use of ABM in epidemiology, ecology, transportation systems, and disaster management.

The behavior of agents is commonly represented through statecharts, which define possible states and transitions among them. Statecharts provide a convenient mechanism for modeling event-driven and time-dependent processes, allowing agents to modify their states according to probabilistic rules, interactions with neighboring entities, or changes in environmental conditions [4]. This approach is particularly useful when studying spreading processes, where the state of one agent may directly affect the evolution of nearby agents.

Epidemic spread is traditionally described using compartmental models in which individuals transition between epidemiological states such as susceptible, infected, and recovered [5], [6]. Although these models provide valuable insights into disease dynamics, they generally assume homogeneous mixing within the population and often neglect variations in contact patterns, mobility, and individual behavior. Agent-based approaches address these limitations by explicitly representing social interactions and behavioral heterogeneity, enabling a more realistic description of disease transmission [7]–[9]. Recent studies have further demonstrated the applicability of agent-based frameworks for incorporating intervention strategies, contact tracing mechanisms, and non-pharmaceutical mitigation measures [16]–[19].

Wildfire propagation can also be considered a spreading process governed by local interactions. In many simulation studies, trees are represented as discrete entities occupying cells within a spatial grid and may transition between states such as intact, burning, and burned. The likelihood that a tree ignites is influenced by several factors, including vegetation density, burning duration, wind conditions, and the characteristics of neighboring cells [21]–[27]. Previous investigations have shown that wildfire dynamics exhibit properties associated with self-organized criticality and percolation phenomena, where relatively small changes in vegetation density may substantially alter the probability of large-scale fire events [22]–[24].

Although epidemic transmission and wildfire propagation are generally investigated within different scientific disciplines, both can be formulated as spreading processes driven by interactions among autonomous agents evolving. From a simulation perspective, both systems share common modeling elements, including discrete agent states, stochastic state transitions, local neighborhood interactions, spatial environments, and scenario-dependent parameters. Consequently, similar agent-based modeling principles can be employed to investigate different spreading phenomena while maintaining a consistent simulation methodology.

Based on these common modeling principles, both simulation models presented in this study were implemented using the AnyLogic simulation platform [33], which provides integrated support for statechart-based agents, stochastic processes, spatial interactions, and scenario management [4]. Employing the same simulation environment and modeling methodology enables a consistent comparative investigation of biological and environmental spreading phenomena while preserving the specific characteristics of each application domain. This unified methodological perspective provides the basis for the comparative analyses presented in the following sections.

A. Common Agent-Based Modeling Methodology

The proposed models follow the same agent-based modeling methodology despite representing different application domains. In both models, the system is composed of autonomous agents situated within a discrete spatial environment. Each agent occupies one state at a given time and changes its state through statechart-based transitions triggered by local interactions, stochastic processes, or predefined simulation rules. The environment defines spatial relationships among neighboring agents, while scenario-specific parameters control interaction probabilities and propagation dynamics. Simulation outputs are obtained by observing the collective behavior emerging from numerous local interactions over time. The adoption of a common modeling methodology facilitates consistent comparative analysis, improves the interpretability of simulation outcomes, and demonstrates the transferability of agent-based modeling principles across different categories of spreading phenomena.

In this study, the term unified refers to the use of a common modeling methodology rather than to a shared mathematical formulation or identical parameter set. Both models follow the same sequence of agent specification, statechart design, local interaction modeling, scenario configuration, simulation execution, and comparative analysis, while their transition mechanisms and parameters remain domain-specific.

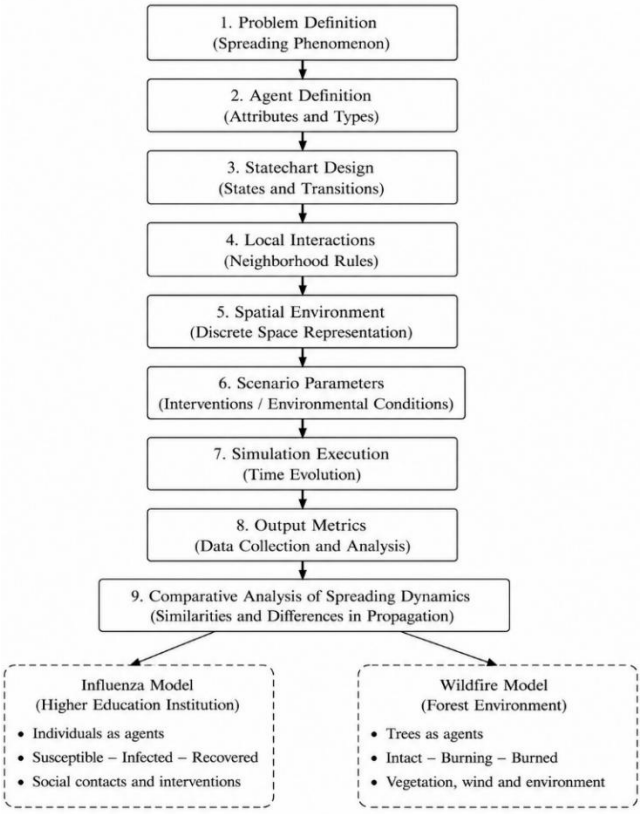

Fig. 1. General workflow of the common agent-based modeling methodology employed in both simulation models.

Fig. 1 summarizes the common agent-based modeling workflow adopted in this study. Although the influenza and wildfire models represent different application domains, both follow the same sequence of problem definition, agent specification, statechart design, local interaction modeling, scenario configuration, simulation execution, and comparative analysis. This workflow defines a reusable modeling procedure in which a new spreading domain can be represented by specifying its agents and states, defining domain-specific transition and local interaction rules, configuring relevant scenario parameters, executing the simulation, and analyzing the resulting system-level behavior. The following sections describe the implementation details of each application while maintaining this common methodological structure.

Although the influenza and wildfire models represent different application domains, they share several common modeling principles that ensure methodological consistency throughout the simulation process. Table I summarizes the principal modeling elements adopted in both agent-based models and highlights the similarities and domain-specific characteristics of each application.

TABLE I. COMPARISON OF THE COMMON MODELING ELEMENTS ADOPTED IN THE INFLUENZA AND WILDFIRE AGENT-BASED SIMULATION MODELS

Modeling Element	Influenza Model	Wildfire Model
Agents	**Students**	**Trees**
State representation	Susceptible, Exposed, Infectious, Recovered	Unburned, Burning, Burned
Environment	Higher education institution	Forest environment
Local interactions	Person-to-person contacts	Neighboring trees
State transitions	Infection, incubation, recovery	Ignition, burning, burnout
Scenario parameters	Vaccination, masks, isolation	Density, wind, burning duration
Output metrics	Epidemic dynamics	Fire propagation dynamics

As shown in Table I, both simulation models follow the same methodological structure despite representing different spreading phenomena. The primary differences relate to the definition of agents, state transitions, and domain-specific parameters, whereas the underlying agent-based modeling principles, statechart implementation, local interactions, and scenario-based experimentation remain consistent. This methodological consistency forms the basis for the detailed model descriptions presented in the following sections.

IV. METHODOLOGY AND SIMULATION SETUP

A. Influenza Transmission Model

Following the common agent-based modeling methodology described in Section III-A, the first application investigates influenza transmission within a higher education institution. The model was implemented in the AnyLogic simulation environment, where students are represented as autonomous agents interacting within a shared environment and transitioning among epidemiological states according to predefined behavioral rules (Fig. 2).

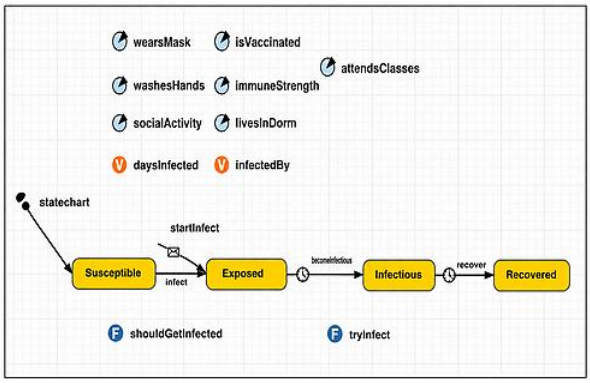

Fig. 2. Statechart of the influenza transmission model.

The implemented statechart consists of four epidemiological states, namely Susceptible, Exposed, Infectious, and Recovered, allowing the representation of an incubation period prior to the onset of infectiousness. State transitions are governed by probabilistic mechanisms describing disease transmission, progression, and recovery. The statechart implementation follows the common modeling workflow presented in Fig. 1,

where individual agent behavior emerges through state transitions triggered by local interactions and stochastic events.

At the beginning of each simulation run, a predefined percentage of students is initialized as infectious, whereas the remaining population is considered susceptible. Disease transmission occurs through interactions between susceptible and infectious individuals. The probability of infection depends on a transmission coefficient that can be adjusted to represent different outbreak conditions. Exposed individuals remain in the incubation state for a specified period before becoming infectious. After the infectious period, agents transition to the recovered state, where temporary immunity is assumed.

The simulation population consisted of 200 students, with three individuals initially infected. The incubation and recovery periods were configured within the ranges of 1–7 and 2–14 days, respectively. Disease transmission was governed by probabilistic interactions between susceptible and infectious agents, with the transmission coefficient controlling the likelihood of infection. The intervention scenarios considered 80% mask compliance, 75% vaccination coverage, and a 70% isolation probability. In the isolation scenario, students maintained an average of twelve daily contacts and could enter isolation only after at least two days in the infectious state.

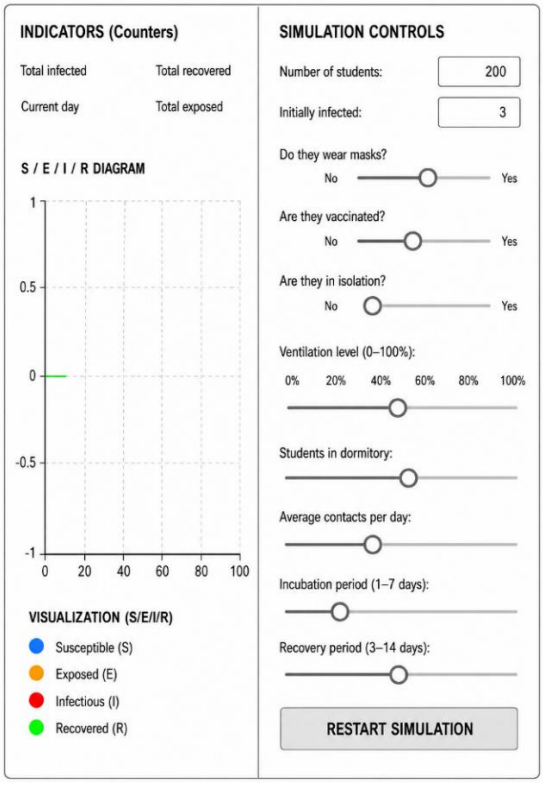

Fig. 3. Simulation environment of the influenza model.

To evaluate the influence of mitigation strategies on epidemic dynamics, several intervention mechanisms were incorporated into the model, including vaccination, mask usage, self-isolation, and reductions in contact frequency. These measures allow the investigation of their impact on epidemic dynamics and facilitate comparative analyses under different mitigation strategies. The simulation environment and the main model parameters used to configure the influenza scenarios are shown in Fig. 3.

B. Wildfire Propagation Model

The second application follows the same agent-based modeling methodology and investigates wildfire propagation within a forest environment. Similar to the influenza model, the wildfire simulation was implemented using statechart-based agents in the AnyLogic platform. Individual trees occupy cells of a two-dimensional spatial grid and interact locally with neighboring trees according to predefined propagation rules (Fig. 4).

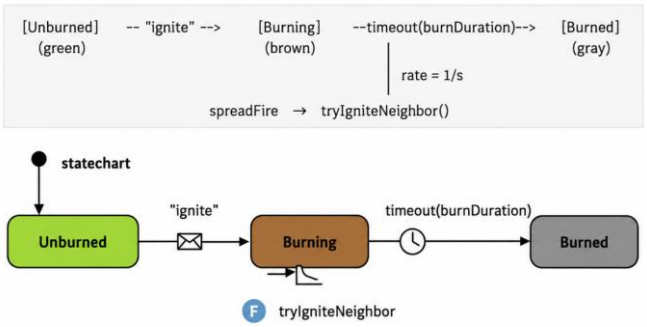

Fig. 4. Statechart of the wildfire propagation model.

Each tree may exist in one of three states: Unburned, Burning, and Burned. State transitions are implemented through an AnyLogic statechart. The wildfire statechart preserves the same state-based modeling philosophy adopted in the influenza model while incorporating domain-specific transition rules associated with fire propagation. A tree enters the burning state upon receiving an ignition message from a neighboring burning tree and remains active for a predefined burning duration before permanently transitioning to the burned state.

Fire propagation occurs locally through interactions among neighboring trees. The ignition probability depends on several factors, including forest density, burning duration, wind speed, and wind direction. Wind effects are incorporated by increasing ignition probabilities in the prevailing wind direction while simultaneously reducing propagation probabilities in the opposite direction.

Forest density, wind speed, wind direction, ignition probability, and burning duration were defined through adjustable simulation parameters accessible via the graphical user interface. These settings enabled the evaluation of wildfire propagation under different environmental conditions. The use of adjustable parameters enabled systematic scenario-based experimentation while maintaining consistency with the common simulation methodology described in Section III-A.

The wildfire environment was represented by a 50 × 50 spatial grid, with a base ignition probability of 0.3 in the illustrated configuration. The experimental scenarios considered forest densities of 0.3, 0.7, and 0.9, wind speeds of 0, 5, and 15 m/s, and burning durations of 2 and 5 simulation time units. Ignition depended on local interactions between neighboring trees, with wind direction modifying the likelihood of propagation along different directions. The complete scenario

configurations and corresponding simulation outcomes are summarized in Table III.

The initial forest configuration and the simulation environment used to configure the wildfire scenarios are shown in Fig. 5.

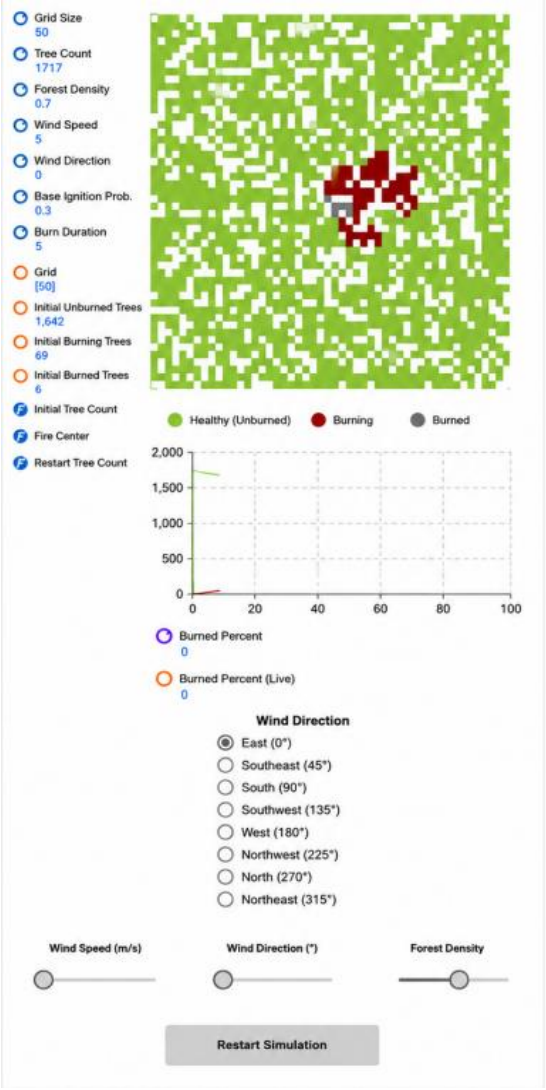

Fig. 5. Initial forest configuration and wildfire simulation environment.

V. Results and Discussion

The results reported in this section correspond to representative simulation runs for each investigated scenario. Because the models include stochastic state transitions, individual runs may produce variations in peak magnitude, timing, and outcomes. Therefore, the reported values should be interpreted as illustrative scenario outcomes rather than statistical estimates of expected system behavior.

A. Epidemic Dynamics Under Different Intervention Strategies

The proposed agent-based influenza transmission model was evaluated under four intervention scenarios designed to investigate the impact of various mitigation measures on epidemic progression within a university environment. The investigated scenarios included a baseline case without interventions, increased mask usage, vaccination, and isolation of infected individuals.

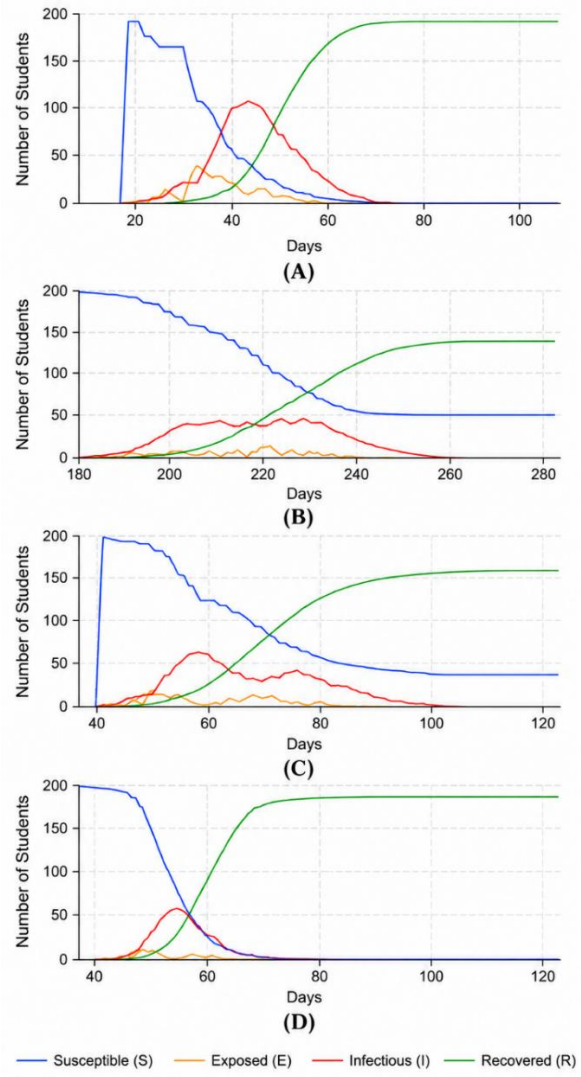

Fig. 6. Temporal evolution of Susceptible (S), Exposed (E), Infectious (I), and Recovered (R) Populations under four intervention scenarios: (A) Baseline scenario without interventions, (B) Mask usage, (C) Vaccination, and (D) Isolation of infected students.

Fig. 6 illustrates the temporal evolution of the SEIR compartments under the investigated intervention strategies. Significant differences in epidemic progression can be observed depending on the applied mitigation measure. The investigated scenarios were selected to evaluate the capability of the common agent-based modeling methodology to represent different intervention strategies using identical modeling principles while varying only domain-specific parameters.

The baseline scenario (Fig. 6A) represents disease transmission without preventive interventions. The epidemic spreads rapidly through the student population, reaching a maximum of approximately 104 simultaneously infectious students around day 15. By the end of the simulation, only six individuals remain susceptible, while 194 students recover from

the disease. These results indicate that approximately 97% of the population experiences infection in the absence of control measures.

The second scenario (Fig. 6B) investigates the effect of increased mask usage, assuming an 80% compliance rate among students. Compared with the baseline scenario, the epidemic peak is considerably reduced to approximately 45 infectious individuals and delayed until around day 50. The number of susceptible individuals at the end of the simulation increases to 52, while 148 students recover. The delayed epidemic peak and flatter epidemic curve suggest that mask usage effectively decreases transmission opportunities and slows disease propagation.

Vaccination was examined in the third scenario (Fig. 6C), assuming vaccination coverage of 75% of the student population. The number of infectious individuals reaches a maximum of approximately 44 students around day 15. Although vaccination substantially suppresses disease transmission, a smaller secondary increase in infectious cases can still be observed. At the end of the simulation, 34 students remain susceptible, while 166 recover from infection. These findings indicate that vaccination significantly improves epidemic control but may not eliminate disease spread among residual susceptible subgroups.

The fourth scenario (Fig. 6D) evaluates the impact of isolation as the sole intervention strategy. The isolation probability was set to 70%, whereas masks and vaccination remained disabled, and students maintained an average of twelve daily contacts. In contrast to masks and vaccination, isolation acts after infection has already occurred. Students may isolate only after being infectious for at least two days, allowing disease transmission during the initial infectious stage. The simulation results demonstrate a peak of approximately 70 infectious students around day 25. By the end of the simulation, 180 students recover, and only 20 remain susceptible. Under this scenario configuration, isolation reduced epidemic spread relative to the baseline, resulting in a peak of approximately 70 infectious students and an attack rate of 90%.

To facilitate comparison among the investigated intervention strategies, the principal epidemiological indicators extracted from the simulations are summarized in Table II.

As shown in Table II, all investigated intervention scenarios produced lower epidemic peaks and attack rates than the baseline scenario under the specific parameter settings considered. The mask scenario (80% compliance) resulted in a peak of 45 infectious individuals and an attack rate of 74%, while the vaccination scenario (75% coverage) produced a peak of 44 infectious individuals and an attack rate of 83%. The isolation scenario (70% isolation probability) resulted in a peak of 70 infectious individuals and an attack rate of 90%. Because these scenarios represent different intervention mechanisms and use different coverage or compliance levels, the results should not be interpreted as a normalized ranking of intervention effectiveness. Instead, they illustrate how the simulated epidemic dynamics changed under the specific intervention configurations investigated in this study.

TABLE II. COMPARATIVE EPIDEMIOLOGICAL INDICATORS OBTAINED FROM FOUR INTERVENTION SCENARIOS

	Intervention Strategy	Peak Infectious	Peak Day	Susceptible at End	Recovered at End	Attack Rate
A	Baseline	104	15	6	194	97.0 %
B	Masks (80%)	45	50	52	148	74.0 %
C	Vaccination (75%)	44	15	34	166	83.0 %
D	Isolation (70%)	70	25	20	180	90.0 %

B. *Wildfire Propagation Analysis*

To evaluate the proposed wildfire propagation model, four representative simulation scenarios were investigated by varying forest density, wind conditions, and burning duration. The resulting fire dynamics are illustrated in Fig. 7.

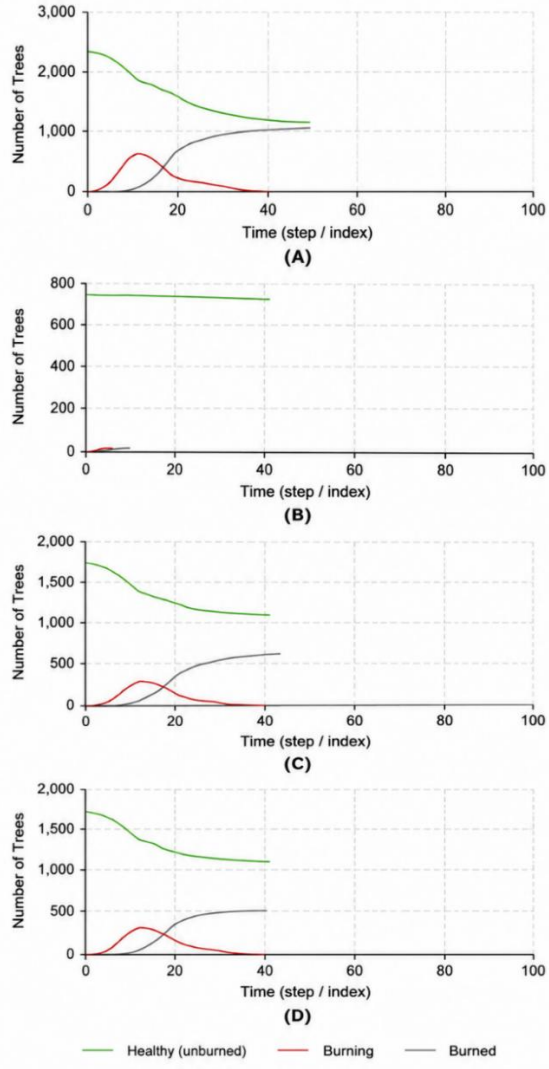

Fig. 7. Temporal evolution of healthy, burning, and burned trees under four representative wildfire propagation scenarios: (A) Dense forest without wind, (B) Sparse forest without wind, (C) Medium-density forest with strong wind, and (D) Reduced burning duration.

The investigated scenarios were selected to illustrate wildfire behavior under different combinations of the principal environmental parameters considered in the model. Consistent with the influenza case study, all wildfire scenarios preserve the same agent-based modeling methodology while using different application-specific environmental parameter settings. The scenarios were not designed as a factorial experiment to isolate the independent effect of each parameter. A summary of the considered configurations is presented in Table III.

TABLE III. COMPARATIVE SUMMARY OF WILDFIRE SIMULATION SCENARIOS

	Forest Density	Wind Speed	Burn Duration	Burned Trees	Peak Burning	Duration (steps)	Pattern
W1	0.9	0	5	1035	501	36	Circular
W2	0.3	0	5	1	3	6	Fragmented
W3	0.7	15 m/s East	5	617	239	46	Eastward
W4	0.7	5 m/s East	2	493	85	24	Reduced

The first scenario (Fig. 7A) represents a dense forest configuration with a vegetation density of 0.9 and no wind influence. Under these conditions, the fire spreads almost uniformly in all directions, producing a nearly circular propagation pattern. The fire spread rapidly through the highly connected vegetation, reaching a peak of approximately 501 simultaneously burning trees around simulation step 8. By the end of the simulation, 1,035 trees had burned, while 1,232 trees remained unaffected, indicating extensive fire damage under dense vegetation conditions. Since neighboring cells are highly connected, the fire rarely encounters natural barriers that would prevent further expansion.

The second scenario (Fig. 7B) investigates a sparse forest characterized by a density of only 0.3. In contrast to the previous case, numerous empty cells interrupt connectivity among trees, frequently leading to early fire extinction. The fire propagation remained highly localized. The maximum number of simultaneously burning trees did not exceed three, and only a single tree became permanently burned by the end of the simulation. These findings indicate that sparse vegetation acts as an effective natural barrier preventing large-scale fire spread.

The third scenario (Fig. 7C) considers a medium forest density of 0.7 and an eastward wind of 15 m/s. Under this parameter combination, the fire developed an elongated pattern directed along the wind axis. The simulation lasted 46 steps and resulted in 617 burned trees, while the maximum number of simultaneously burning trees reached approximately 239 around simulation step 13. Because this scenario differs from the no-wind scenarios in more than one parameter setting, the observed propagation pattern should be interpreted as specific to the investigated configuration rather than as an isolated estimate of the wind effect.

The final scenario (Fig. 7D) considers a forest density of 0.7, an eastward wind speed of 5 m/s, and a burning duration of 2 simulation time units. Under this parameter combination, 493 trees were burned, the maximum number of simultaneously burning trees was 85, and the propagation duration was 24 simulation steps. In comparison, Scenario W3 resulted in 617 burned trees, a peak of 239 simultaneously burning trees, and a duration of 46 simulation steps. Because W3 and W4 differ in both wind speed and burning duration, the observed differences cannot be attributed to burning duration alone.

Overall, the investigated scenarios produced substantial differences in fire extent, peak fire intensity, and propagation duration under different combinations of vegetation density, wind conditions, and burning duration. Because multiple parameters vary across the scenarios, these results describe scenario-specific propagation patterns rather than independent effects of individual environmental factors.

C. Comparative Discussion

The two developed simulation models demonstrate that different spreading phenomena can be investigated using a common agent-based modeling methodology while preserving their domain-specific characteristics. Although the biological and environmental processes considered in this study differ substantially in their underlying mechanisms, both follow identical modeling principles regarding autonomous agents, stochastic state transitions, local interactions, and scenario-based experimentation.

The influenza model considers students as individual agents interacting through social contacts and transitioning among susceptible, exposed, infectious, and recovered states. In contrast, the wildfire model represents trees as stationary agents whose states evolve from unburned to burning and eventually to burned. Despite these differences, both models employ statechart-based agent representations and incorporate probabilistic mechanisms governing state transitions.

To emphasize similarities and differences between the two simulation approaches, a comparative overview is presented in Table IV.

TABLE IV. COMPARATIVE CHARACTERISTICS OF THE DEVELOPED AGENT-BASED MODELS

Characteristic	Influenza Model	Wildfire Model
Simulation Platform	AnyLogic	AnyLogic
Modeling Approach	Agent-Based Modeling	Agent-Based Modeling
Agent Type	Student	Tree
State Representation	SEIR	Unburned–Burning–Burned
Statechart Implementation	Yes	Yes
Stochastic Components	Yes	Yes
Spatial Representation	Social interaction network	Two-dimensional grid
Main Influencing Factors	Masks, vaccination, isolation	Forest density, wind, burning duration
Main Performance Indicator	Peak infectious population	Percentage of burned trees
Intervention Strategies	Yes	No
Primary Objective	Epidemic mitigation	Wildfire propagation assessment

Table IV further demonstrates that, despite substantial differences in the modeled systems, the two simulation models preserve a consistent methodological structure. The principal distinctions arise from application-specific agents, states, and parameters, whereas the underlying simulation methodology remains identical.

The results obtained from both models indicate substantial differences in propagation dynamics across the investigated scenario settings. Similar observations have been reported in recent wildfire propagation studies employing calibrated simulation environments and irregular computational grids [26], [27]. In the epidemic simulations, preventive interventions substantially modify the magnitude and timing of epidemic peaks, while in the wildfire simulations relatively small variations in vegetation connectivity, wind conditions, and burning duration can lead to pronounced differences in fire extent and propagation patterns.

The comparison further demonstrates the flexibility of agent-based modeling for investigating complex dynamic systems characterized by heterogeneity, local interactions, and nonlinear behavior. By allowing individual entities to operate autonomously and interact according to predefined rules, agent-based models provide a flexible framework for studying spreading processes that are often difficult to analyze analytically or reproduce experimentally.

TABLE V. QUALITATIVE EFFECTS OF KEY PARAMETERS IN THE INVESTIGATED SIMULATION SCENARIOS

Model	Parameter	Observed Effect in the Investigated Scenario
Influenza	Mask Usage	Reduces transmission probability and delays epidemic peak
Influenza	Vaccination Coverage	Decreases the number of infectious individuals and increases population immunity
Influenza	Isolation Rate	Limits contacts after infection but acts with a delay
Wildfire	Forest Density	Determines connectivity among trees and extent of fire spread
Wildfire	Wind Speed	Accelerates directional fire propagation
Wildfire	Burning Duration	Influences secondary ignitions and final burned area

Table V summarizes the qualitative effects observed for the key parameters under the investigated simulation settings. In the epidemic model, the investigated mask, vaccination, and isolation scenarios produced different propagation outcomes under their respective parameter settings. Similarly, in the wildfire model, different combinations of forest density, wind conditions, and burning duration produced distinct fire propagation patterns. These observations are scenario-specific and should not be interpreted as a quantitative ranking of parameter influence. Nevertheless, they illustrate how agent-based simulation can support the comparative exploration of alternative parameter configurations in complex adaptive systems.

Several limitations should be acknowledged. The proposed models rely on simplified interaction mechanisms and do not incorporate empirical calibration, realistic mobility patterns, heterogeneous landscapes, or high-resolution meteorological datasets. Accordingly, the reported results should be interpreted as simulation-based observations under the investigated parameter settings rather than as empirically validated predictions of real-world epidemic or wildfire behavior. In addition, the present analysis is based on representative simulation runs and does not quantify stochastic variability through repeated runs or confidence intervals. Future work should employ multiple replications for each scenario and report statistical measures of variability to assess the robustness of the observed propagation patterns. The study does not include quantitative benchmarking against conventional domain-specific approaches, such as compartmental epidemic models or cellular automata-based wildfire models; therefore, no claims are made regarding superior predictive accuracy, computational efficiency, or model fidelity. Furthermore, the study focuses on representative simulation scenarios rather than predictive forecasting. Further extensions may integrate real-world datasets and calibration procedures, employ systematic parameter sweeps, sensitivity analyses, and factorial experimental designs to quantify the individual and interaction effects of forest density, wind conditions, and burning duration, and extend the methodology to additional categories of spreading phenomena, including information diffusion and cascading infrastructure failures.

VI. CONCLUSION

This study presented a common agent-based modeling methodology, implemented in the AnyLogic simulation environment, for investigating different spreading phenomena in complex adaptive systems. The proposed methodology was demonstrated through two representative application domains: influenza transmission within a higher education institution and wildfire propagation in a forest environment. Although the underlying mechanisms of these processes differ substantially, both models were developed using consistent modeling principles based on autonomous agents, statechart-driven behavior, stochastic state transitions, local interactions, and scenario-based experimentation.

The influenza simulations demonstrated that the investigated mask, vaccination, and isolation scenarios reduced epidemic intensity compared with the baseline under the specific parameter settings considered. Because the interventions were implemented using different mechanisms and coverage levels, these results represent scenario-specific outcomes rather than a normalized comparison of intervention effectiveness. These findings illustrate the potential role of preventive measures in modifying epidemic dynamics within the simulated educational environment.

The wildfire simulations produced substantially different propagation patterns across the investigated combinations of vegetation density, wind conditions, and burning duration. Dense and sparse forest configurations showed markedly different fire-spread patterns, while the scenario including strong eastward wind exhibited directional propagation. Because multiple parameters varied across some scenarios, the observed differences should be interpreted as scenario-specific outcomes rather than as isolated effects of individual environmental factors.

The comparative analysis demonstrated that, despite representing different scientific domains, both models exhibit

common propagation characteristics arising from local interactions among autonomous agents operating under stochastic conditions. The successful application of the same modeling methodology to two substantially different spreading phenomena demonstrates its consistency and transferability across different application domains. This finding highlights the potential of agent-based modeling as a versatile simulation methodology for analyzing complex adaptive systems characterized by heterogeneous entities, nonlinear dynamics, and emergent behavior.

Future research may extend the proposed methodology by incorporating empirical calibration, realistic mobility patterns, heterogeneous landscapes, high-resolution environmental and meteorological datasets, and additional categories of spreading phenomena, such as information diffusion, cascading infrastructure failures, and ecological invasion processes. Such extensions would further improve the generality and practical applicability of the proposed modeling approach.

Play-Centric Design and Usability Evaluation of a Block-Based Programming Serious Game for Low Vision Children

Huang Sheng, Chau Kien Tsong*, Wan Ahmad Jaafar Wan Yahaya
Universiti Sains Malaysia, Malaysia

***Abstract*—Serious games are effective tools for learning beyond entertainment, yet children with low vision face obstacles when playing block-based programming games because these environments rely on small graphical elements, low colour contrast, and drag-and-drop interaction, a barrier specific to block-based programming that does not arise in other game genres. This study presents the design and usability evaluation of a block-based programming serious game for teaching sequences, loops, and conditionals to low-vision children aged seven years old. Accessibility elements were implemented in the prototype, namely screen design, multimedia, keyboard-based interaction replacing drag-and-drop, and language. Usability testing and a pre-test and post-test were conducted with sixteen children in matched experimental and control groups of eight, the control group using a feature-reduced baseline version, with results reported descriptively. The accessible version obtained a Good overall usability score of 3.80, against a Weak score of 1.65 for the baseline. Only 25 per cent of control participants independently reached all three target concepts, compared with 100 per cent in the accessible version. Because only baseline participants who reached the target concepts were compared, the learning gain difference is a conservative estimate of the accessibility effect.**

Keywords*—Serious game; block-based programming; low vision; accessibility; usability testing; computational thinking; assistive technology

I. Introduction

Nowadays, information and communication technologies (ICT) are used in education. We can find a lot of educational applications that can help young learners learn. Several ICT applications are on the market, such as e-books, multimedia courseware, and games [1][2]. Gaming is a very popular activity enjoyed by children. Thus, a serious game is the most promising tool for helping children learn. A serious game is used beyond entertainment [1]. Serious games are powerful tools for building language, science, math, and computing knowledge and skills. This educational value has been demonstrated across contexts including early childhood education [22] and STEM learning more broadly [24]. Despite a growing number of studies on using serious games for learning, children with visual impairments have obstacles when playing the games. There are two categories of visual impairment: blindness and low vision. Low vision children have a visual impairments that can be assisted with assistive technology. The World Health Organisation defines low vision as visual acuity between 20/70 and 20/400, with a possible correction of 20 degrees or less [31]. Low vision children have obstacles accessing graphical elements in games. Prior studies indicate that low vision children face several accessibility issues, such as visual, animation, audio, and navigation obstacles [9], [11]. This is consistent with broader evidence that low vision affects reading behaviour [17] and the interpretation of visual information more generally [18]. They need to look at graphical elements from a very close distance because the size of the text and graphics is small. The colour contrast between the graphics and background is often low. They also have difficulty navigating the menus and buttons in games, and fast animation movements affect their vision when playing games.

Among educational applications, block-based programming environments such as Scratch have become the most popular tool for introducing young children to computational thinking, because they allow children to build instructions by assembling visual blocks instead of typing code [4], [21]. The use of such tools to build computational thinking and programming skills has been demonstrated across K-12 educational settings [25], [26]. Unlike most other educational applications, however, block-based programming environments depend on an interaction method that other serious game genres do not require: drag-and-drop, where children must click, hold, and drag a block precisely into place to construct a program. This dependence on drag-and-drop is a barrier specific to block-based programming. This is consistent with accessibility issues documented across block-based programming environments more broadly [20]. A mathematics or language serious game can be made usable for low vision children through screen design and multimedia adaptations alone [3], but a block-based programming game remains unusable if children cannot physically perform the drag-and-drop action, regardless of how large or high-contrast the blocks are made. Thus, to ensure low-vision children can play the game, a block-based programming serious game for learning sequences, loops, and conditionals is developed for low-vision children aged seven years old. The game consists of three levels of programming tasks, based on introductory computational thinking content appropriate for Year 1 pupils, namely ordering instructions (sequences), repeating instructions (loops), and if-then decision making (conditionals). These constructs are consistent with the core computational-thinking skills assessed in prior block-based programming research [14].

Serious games should be easily accessible to low vision children. The game design should be flexible, with an interface adapted to the accessibility requirements of low vision children.

*Corresponding author.

To enhance the game's accessibility for low vision children, accessibility elements have been implemented in the serious game prototype. Those elements are screen design (buttons, menus, and navigation), multimedia (text, graphics, and audio), interaction method, and language. The children can set the appropriate background colour and contrast level based on their vision level. The text size is large and adjustable. The background colour has a high colour contrast, and bright colours and large graphics are implemented in the game. Background audio and navigation cues are provided so children can identify their position on the screen and understand the game's instructions without relying on vision alone. Most importantly, the conventional drag-and-drop interaction used to assemble programming blocks is replaced with a keyboard-based selection method: children navigate the interface using arrow keys, and press Enter to select and place a block, removing the need for precise cursor control. This design choice is consistent with accessible input approaches explored for other populations with fine motor or visual constraints [19]. A feature-reduced baseline version of the same game, without these accessibility elements, is also developed to serve as a comparison during usability testing.

Upon completion of the serious game, usability testing is conducted to identify the accessibility of the serious game for low-vision children based on the usability level, and a pre-test/post-test is conducted to identify whether the game helps low-vision children understand the target programming concepts.

Thus, this study presents the design and usability testing of a block-based programming serious game prototype developed specifically for low vision children aged seven years old. The serious game is developed based on the accessibility requirements of low vision children, refined through pilot testing and expert heuristic evaluation prior to user testing. The effectiveness, efficiency, and user satisfaction of the serious game are tested in the usability testing, and the learning outcome of the game is tested using a pre-test and post-test benchmarked against a feature-reduced baseline version. The observation technique is used for analysing the serious game. The usability testing aims to identify the serious game's usability level and learning effectiveness for low-vision children.

This study is organised as follows: Section I presents the introduction, while Section II describes the related work. Section III describes the methodology, and Section IV and Section V discuss the results and discussion, respectively, while Section VI presents the conclusion and plan for future work.

II. Related Work

The International Organization for Standardization (ISO) 9241-11 (1998) defines usability as the ability of a product to be used by users to accomplish certain goals effectively, efficiently, and with user satisfaction [30]. Usability also refers to whether a product is easy to use. Based on the ISO 9241-11 definition, usability consists of the following components:

- Effectiveness: The accuracy and completeness with which a user can achieve a certain goal in a certain environment.
- Efficiency: The effort the user gives to complete a task and achieve the objective of using an application or system.
- User Satisfaction: User comfort and acceptance of the system.

Usability testing is conducted to identify usability problems before releasing the serious game in its real context. There is some overlap between the concepts of usability and accessibility: accessibility enables users to access ICT applications independently without accounting for their disability, while usability refers to the ability of the ICT application to carry out the intended function effectively, efficiently, and with satisfaction when used by users in general [30]. Therefore, accessibility specifically refers to disabled users, while usability refers to the general population. Usability testing is also considered suitable for assessing ICT applications for accessibility [7].

Prior research has proposed a serious-game accessibility design model consisting of three components, namely accessibility, game design, and pedagogy [11], and implemented accessibility elements including screen design, multimedia, object motion, and language in a mathematics serious game for low vision children, refined using a play-centric design approach through a low-fidelity prototype and pilot feedback from low vision children [8]. Usability testing of this game, conducted through direct observation with fifteen low vision children, reported good usability scores across effectiveness (4.74), efficiency (4.55), and user satisfaction (4.92), with an overall usability score of 4.76 [3]. These findings show that accessibility elements such as screen design, multimedia, language, and object motion are important in increasing the usability of serious games for low vision children. However, this study focused on a mathematics game, in which children select and tap answers on screen; it does not address the additional interaction barrier present in block-based programming, where children are required to drag and connect blocks to construct a sequence of instructions, nor does it assess whether use of the game was associated with a measurable gain in the target academic content.

Block-based programming languages have become the dominant approach to introductory programming education because they lower the syntactic barrier to entry for young learners [4]. Prior efforts to make block-based programming accessible have largely targeted children who are blind: Blocks4All, an iPad-based block-based programming environment, replaces the visual programming canvas with touchscreen exploration and VoiceOver audio feedback, and was evaluated with children who are blind or have visual impairments controlling a physical robot [5]. This and related approaches are designed around the assumption that the user has no usable vision, and therefore do not directly address the residual-vision use case of low vision children, for whom enlarged and high-contrast visual elements, combined with reduced dependence on fine motor precision rather than a fully non-visual interface, are more appropriate.

A representative sample of users must conduct usability testing because users are different and have different problems [6]. Suitable usability testing methods should be considered when planning testing with children. Usability testing with children consists of introspection, direct observation, thinking aloud, and interaction. Direct observation is used to observe users as they perform their tasks, and this technique has been recognised as one of the best techniques for usability testing with young children, since it does not depend on children's ability to verbalise their experience [6], [15]. Satisfaction with children is commonly measured using simplified emoticon-based scales, such as like, neutral, and dislike, to observe the user's reaction to the game [3].

Accessibility research more broadly has also been reported within this journal, for example in evaluations of web accessibility barriers [9] and usability evaluations of interfaces for specific user populations [12][13], reflecting the value of usability testing as a method for surfacing accessibility problems that are not apparent from design review alone. While prior studies have evaluated the usability of serious games for low vision children, usability testing alone does not establish whether the target educational content was learned. Coupling usability testing with a pre-test/post-test learning outcome assessment allows a study to determine not only whether low vision children can use a serious game, but whether using it is associated with a gain in the knowledge the game is intended to teach.

III. METHODOLOGY

The usability testing method used in this study is direct observation. The observation method is conducted to evaluate the user experience of the product by observing users carrying out the tasks provided. Observations are conducted based on effectiveness, efficiency, and user satisfaction. User satisfaction is subjective; thus, interviews are also conducted with low-vision children to obtain feedback regarding their satisfaction level with the tested serious game. During the interview, emoticons (like, neutral, dislike) are prepared to observe the user's reaction to the game. In addition to usability testing, a pre-test and post-test are conducted to identify whether the game is associated with a gain in understanding of sequences, loops, and conditionals. The overall study follows a three-phase process: 1) design and iterative refinement of the game prototype, incorporating pilot testing with children and expert heuristic evaluation; 2) recruitment and assignment of participants; and 3) usability and learning-outcome testing.

A. Game Design and Prototype Refinement

The game is designed following a three-component accessibility model, namely accessibility, game design, and pedagogy [11]. A play-centric design approach is adopted, beginning with a low-fidelity prototype refined through pilot feedback from three to five low-vision children, consistent with the play-centric prototyping approach used in prior serious-game design research for this population [8].

Table I shows the accessibility elements implemented in the accessible version of the game, and the corresponding elements omitted in the feature-reduced baseline version used for comparison during testing.

Both versions shared the same level content, learning objectives, and progression structure. They differed only in the presence or absence of the full set of accessibility elements summarised in Table I (screen design, multimedia, interaction method, and text). Consequently, any systematic differences observed between the experimental and control groups can be attributed to the accessibility package, rather than to the keyboard-based interaction method in isolation.

TABLE I. ACCESSIBILITY ELEMENTS IN THE ACCESSIBLE AND BASELINE VERSIONS

Element	Accessible version	Baseline version
Screen design	Large, adjustable buttons and menus	Standard, fixed-size buttons and menus
Multimedia	High-contrast graphics, adjustable colour scheme, audio feedback	Standard-contrast graphics, no audio feedback
Interaction	Keyboard-based selection (arrow keys + Enter)	Mouse-based drag-and-drop
Text	Large, adjustable font size	Standard, fixed font size

Note: The accessible version differs from the baseline version by the full set of accessibility adaptations listed above. Differences in outcomes between the two versions are therefore attributable to the combined accessibility package rather than to any single element in isolation.

The baseline version is intended as a credible feature-reduced comparator rather than a deliberately inaccessible interface: it retains the same learning content, level structure, narrative theme, and progression sequence as the accessible version, and systematically omits only the accessibility elements listed in Table I (large, adjustable buttons and menus; high-contrast graphics; adjustable colour schemes; audio feedback; keyboard-based selection; and large, adjustable text). This design allows any observed differences in usability scores, concept-exposure rates, and learning gains between the two groups to be attributed to the presence or absence of the accessibility package, rather than to differences in pedagogical content or task difficulty.

Following pilot testing, the refined prototype is submitted to an expert heuristic evaluation prior to full user testing. Four experts in human-computer interaction, special education, and game design independently evaluate the prototype using two heuristic sets: game heuristics (challenge, reward, goals, storyline) and pedagogical heuristics (learning objectives, learning theory, content alignment), and complete a structured evaluation questionnaire with improvement recommendations. This heuristic evaluation approach follows methods developed specifically for assessing usability and user experience in children's digital tools [16]. Recommendations arising from this evaluation are consolidated and used to guide a second round of prototype refinement before the prototype is used in the user testing phase.

The serious game user interface, incorporating the accessibility elements described above, is depicted in Fig. 1.

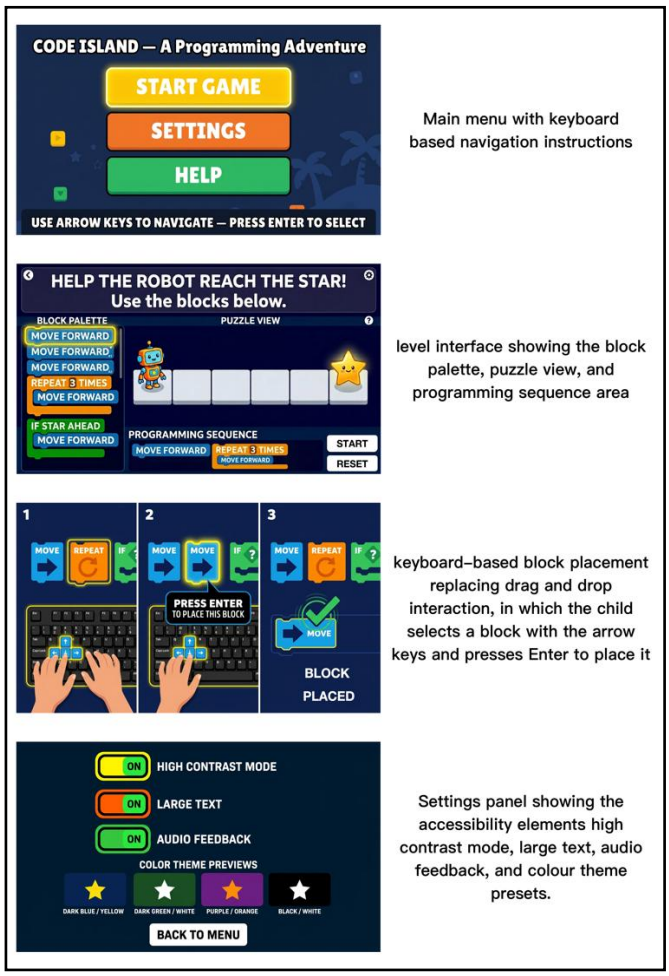

Fig. 1. Serious game user interface.

B. Participants

This study uses a selected study sample recruited from a special education school. Low vision is defined according to World Health Organisation criteria as visual acuity between 20/70 and 20/400, with a possible correction of 20 degrees or less [31], verified through participants' school medical records. This testing involves low vision children aged seven years old, assigned to an experimental group using the accessible version of the game and a control group using the feature-reduced baseline version, matched by age, prior programming or game experience, and level of visual acuity. This study was conducted in accordance with the principles of the Declaration of Helsinki. Ethical approval for this multi-centre study was obtained from the institutional review boards corresponding to the authors' respective affiliations: the Jawatankuasa Etika Penyelidikan Manusia, Universiti Sains Malaysia (No. USM/JEPeM/PP/26070645), for all authors from Universiti Sains Malaysia, and the South China Normal University Ethics Approval Certificate for Research Involving Human Subjects (No. SCNU-2026-039), for the author also affiliated with South China Normal University. To conduct this testing, ethics that the researcher must follow are observed: consent from parents or guardians is required before testing to ensure the study meets research guidelines and ethics, the purpose of the research is explained to the teachers involved, and children are informed of their right to withdraw at any time. Both groups receive the same fixed session duration and the same level of researcher presence throughout testing, so that any difference observed between groups can be attributed to the accessibility adaptations rather than to differences in attention received or to the basic novelty of encountering an unfamiliar digital tool.

C. Usability Testing Procedures

The activities involved in usability testing include determining the testing objective, preparing the instruments and testing tools, identifying the task scenario, preparing the testing checklist, and measuring usability. The testing procedure is further explained in the following sections.

1) Determination of testing objective: This usability testing is conducted to verify the accessibility of the serious game to low-vision children. The evaluation is conducted based on the ISO 9241-11 definition, which covers effectiveness, efficiency, and user satisfaction concerning the serious game [30].

2) Testing instruments and testing tools preparation: The testing instruments consist of the accessible and baseline serious game prototypes, a usability testing task list, an observation checklist, and audio and screen recording tools.

3) Identify task scenarios: Usability testing is conducted by giving the user a task scenario while the user plays the game, prepared according to the game's screens, such as the start screen, the level screens, and the task screen within each level.

4) Testing checklist preparation: A checklist is prepared based on the usability constructs of effectiveness, efficiency, and user satisfaction [30], covering the accessibility elements shown in Table I.

5) Measurement of usability testing: The measurement of effectiveness, efficiency, and user satisfaction is conducted using a usability score, following the scoring approach used in prior serious-game usability research [3].

6) Effectiveness measurement: If a task is completed successfully, a score of 5.0 is marked on the effectiveness checklist item. If the task is half completed, a score of 2.5 is marked; if the task is not completed, a score of 0 is marked. The usability score for effectiveness, X, is formulated as:

$$X = \frac{\Sigma\ score\ for\ each\ effectiveness\ checklist\ item}{total\ effectiveness\ checklist\ items} \quad (1)$$

7) Efficiency measurement: Efficiency is measured based on the time taken to complete the task relative to the average task completion time. The average task completion time used as the scoring benchmark is established separately for each version (accessible and baseline) from the pilot study described in Section III-C6, to account for the difference in interaction speed between the keyboard-based and mouse-based interaction methods; each level's benchmark is computed as the mean completion time recorded for that level across the pilot sample. If the time taken is equal to or faster than the average, a score of 5.0 is marked; if slower, a score of 2.5 is marked; if the task fails, a score of 0 is marked. The usability score for efficiency, X, is formulated as:

$$X = \frac{\sum \ score \ for \ each \ efficiency \ checklist \ item}{total \ efficiency \ checklist \ items} \quad (2)$$

8) User satisfaction measurement: A score of 5.0 is marked if a child's reaction is "like"; 2.5 if "neutral"; and 0 if "dislike". The usability score for user satisfaction, X, is formulated as:

$$X = \frac{\sum \ score \ for \ each \ satisfaction \ checklist \ item}{total \ satisfaction \ checklist \ items} \quad (3)$$

The average value of each usability category is considered the score for that category, and the overall usability score is the average of the three category scores. This scoring approach is consistent with psychometric usability and acceptability scales developed for children and adolescent users [23]. Table II shows the interpretation of the overall usability score, following the interpretation bands used in prior research [3].

TABLE II. USABILITY SCORE INTERPRETATION

Weak	Moderately Good	Good
$0 \leq x \leq 2.49$	$2.5 \leq x \leq 3.49$	$3.5 \leq x \leq 5.0$

9) Implementation of usability test: A pilot study is conducted on the instrument to test its reliability before it is used in the actual testing, involving three to five low-vision children, distinct from the pilot testing conducted during prototype refinement. During usability testing, children play the game with minimal researcher presence; no instructional assistance is provided during the session, so that the effectiveness, efficiency, and satisfaction scores reflect the accessibility of the game itself rather than researcher intervention. Because young children may not spontaneously ask to stop an activity even when struggling, the session is not left to run purely on the child's initiative to withdraw: the researcher proactively pauses the session and checks in with the child if either of the following is observed: no measurable progress for three consecutive minutes, or five consecutive failed attempts at the same step without progression, at which point the child is asked whether they would like to continue or take a break, and a break or early termination is offered accordingly. This check-in is in addition to, not instead of, immediate termination upon overt signs of distress. Control group participants are offered the opportunity to try the accessible version of the game after their session has ended. A screen recorder and camera are used to record testing sessions, and researchers observe and record children's actions on the provided task scenario checklist, which is then transferred to the usability checklist. The data collected are analysed using a descriptive analysis method.

D. Learning Outcome Assessment

In addition to usability testing, a pre-test and post-test are administered to identify whether use of the game is associated with a gain in understanding of sequences, loops, and conditionals.

1) Instrument: Each pre-test and post-test consisted of nine items organised into three equal sections corresponding to the three target concepts: three items on sequences, in which children arranged or identified the correct order of a short series of action steps to complete a simple path; three items on loops, in which children identified or constructed the correct repeating pattern needed to complete a repeated action; and three items on conditionals, in which children selected the appropriate if-then rule to make a character respond differently under two conditions. Each correct response was awarded one point, with no partial credit for individual items, yielding a maximum possible score of 9 on both the pre-test and the post-test. The pre-test and post-test are administered one-on-one, in oral format, accompanied by large, high-contrast visual aids, consistent with the accessibility elements applied to the game itself. Equivalent item sets are used for the pre-test and post-test, differing only in surface-level details such as character names, object colours, and path layouts, to reduce practice effects. The item set is reviewed by a special education teacher and a computer science educator for alignment with the target concepts, age-appropriateness, and clarity for oral administration.

2) Procedure: Both the experimental group and the control group complete the pre-test before their assigned game session and the post-test immediately afterwards. Learning gain is calculated as the difference between the post-test and pre-test scores.

3) Concept-exposure criterion and analysis: For the experimental group, all participants are expected to reach the levels covering all three core concepts within the session and are included in the learning gain analysis. For the control group, only participants who independently reach these levels are included; participants who do not reach concept exposure are excluded from the learning gain comparison, but their outcome-how many control participants did and did not reach concept exposure, and at which level they stopped is retained and reported as usability evidence in its own right, since it directly quantifies the severity of the barriers present in the baseline environment. If the number of control group participants who independently reach concept exposure is fewer than three, group-level means are not reported for this subgroup; instead, the individual pre-test and post-test scores of these participants are reported as case data. Because the participants who reach concept exposure independently are not representative of the control group as assigned, they are more likely to be those with relatively milder visual impairment, better fine motor control, or prior exposure to similar interfaces; any comparison between this subgroup and the experimental group is interpreted as a conservative estimate of the accessibility effect: the true gap between the accessible and baseline conditions is likely larger than the reported comparison suggests. Given the exploratory nature of this study and the anticipated small sample size, learning gain and usability scores are reported descriptively (means, standard deviations, frequencies); no inferential statistical tests are performed. A non-parametric procedure such as the Wilcoxon signed-rank test was considered as an exploratory measure for the matched-pair learning-gain comparison; however, it is not feasible here because six of the

eight matched pairs are incomplete for this comparison, as the corresponding control-group participant did not reach concept exposure (Section IV-D). A matched-pairs analysis restricted to the two complete pairs would be too small to yield an interpretable test statistic, even as an exploratory measure, and is therefore not reported.

IV. Results

This section reports the results of the usability testing and the pre-test/post-test learning outcome assessment. Consistent with the exploratory design and small sample size described in Section III-D3, all usability scores, learning gains, and event counts are reported descriptively using means, standard deviations, and frequencies; no inferential statistical tests are performed. The results are presented in the order of the participant characteristics, the expert heuristic evaluation conducted prior to user testing, the usability scores, the concept-exposure outcomes for the control group, the learning outcome results, the termination-criterion events, and the inter-rater reliability of the learning-outcome scoring.

A. Participants

Table III shows the demographic and matching characteristics of the participants recruited for this study.

TABLE III. Participant Characteristics and Group Assignment

ID	Group	Matched pair	Age (months)	Visual acuity (decimal)	Prior experience	Sex
P01	Experimental	M01	83	0.10	Minimal	M
P02	Control	M01	84	0.12	Minimal	M
P03	Experimental	M02	87	0.08	None	F
P04	Control	M02	86	0.10	None	F
P05	Experimental	M03	80	0.15	Some	M
P06	Control	M03	81	0.13	Some	M
P07	Experimental	M04	89	0.05	Minimal	F
P08	Control	M04	88	0.07	Minimal	F
P09	Experimental	M05	84	0.11	None	M
P10	Control	M05	83	0.09	None	M
P11	Experimental	M06	86	0.14	Minimal	F
P12	Control	M06	87	0.12	Minimal	F
P13	Experimental	M07	79	0.10	Some	M
P14	Control	M07	80	0.11	Some	M
P15	Experimental	M08	90	0.06	None	F
P16	Control	M08	89	0.08	None	F
Total (Experimental, n=8)		8 pairs	Range 79–90 (M≈84.8)	0.05–0.15, all WHO-confirmed low vision	None=3, Minimal=3, Some=2, (see note)	M=4, F=4
Total (Control, n=8)			Range 80–89 (M≈84.8)	0.07–0.13, all WHO-confirmed low vision	None=3, Minimal=3, Some=2, (see note)	M=4, F=4

Note: All 16 participants were assigned in eight age-, sex-, prior-experience-, and visual-acuity-matched pairs (one experimental, one control participant per pair), consistent with the matching procedure described in Section III-B. Prior experience distribution across the full sample (both groups combined) was None=6, Minimal=6, Some=4. Visual acuity was confirmed against school medical records for all participants and fell within the WHO low vision range in every case.

B. Expert Heuristic Evaluation

Table IV shows the results of the expert heuristic evaluation conducted prior to user testing, covering game heuristics and pedagogical heuristics, together with the resulting prototype refinements.

As shown in Table IV, all seven heuristic dimensions received mean expert ratings between 3.8 and 4.5 on the 5-point scale, indicating that the prototype was rated favourably across both the game and pedagogical heuristics prior to user testing. The lowest-rated dimension was Challenge (3.8), reflecting expert concern about the difficulty increase between the Loops and Conditionals concepts, which was addressed by adding an intermediate practice level before the Conditionals concept. The Goals and Learning objectives dimensions received the highest ratings (4.5 each), and the associated recommendations, together with those for the remaining dimensions, were implemented as concrete refinements to the prototype before the user testing phase. Because each recommendation was translated into a specific design change, the version subsequently evaluated in the usability testing already incorporated the improvements identified during the heuristic evaluation.

TABLE IV. EXPERT HEURISTIC EVALUATION RESULTS

Heuristic dimension	Mean expert rating	Key recommendation	Refinement implemented
Challenge	3.8 (0.5)	Reduce the difficulty jump from loops to conditionals	Added an intermediate practice level before conditionals
Reward	4.3 (0.5)	Make success feedback more salient for low vision users	Added a distinct success chime and large green checkmark animation
Goals	4.5 (0.6)	Clarify the learning goal of each level more explicitly	Added a short audio and large-text goal statement at the start of every level
Storyline	4.0 (0.8)	Strengthen narrative continuity across the three concepts	Linked levels with a simple character-progress story and a consistent visual theme
Learning objectives	4.5 (0.6)	Make the three target concepts more explicitly visible	Display the current concept name (Sequences, Loops, Conditionals) in large high-contrast text on each level screen
Learning theory alignment	4.2 (0.5)	Better support progressive scaffolding of computational thinking constructs.	Inserted guided practice tasks that reuse previous concept blocks before introducing the next
Content alignment	4.3 (0.5)	Ensure block vocabulary matches Year-1 curriculum language	Simplified block labels and added optional audio read-aloud of each block name

Note: Each dimension was rated by the four experts on a 5-point scale (1 = poor, 5 = excellent); values are reported as mean (SD) across experts. Game heuristics and pedagogical heuristics were evaluated using two separate structured checklists, as described in Section III-A. Each key recommendation was addressed through the corresponding refinement prior to the user testing phase.

C. Usability Results

Table V shows the effectiveness, efficiency, and user satisfaction scores for the experimental and control groups, calculated using Eq. (1)-(3) and interpreted using the bands in Table II, reported per level.

TABLE V. EFFECTIVENESS, EFFICIENCY, AND SATISFACTION SCORES BY GROUP AND LEVEL

Group	Level	Effectiveness (SD)	Efficiency (SD)	Satisfaction (SD)	Overall score	Interpretation
Experimental	1 – Sequences	4.54 (0.81)	4.22 (0.99)	4.54 (0.81)	4.43	Good
Experimental	2 – Loops	3.90 (1.11)	3.59 (1.19)	3.90 (1.11)	3.80	Good
Experimental	3 – Conditionals	3.29 (1.23)	2.97 (1.27)	3.29 (1.23)	3.18	Moderately Good
Experimental	Overall	3.91 (1.12)	3.60 (1.18)	3.91 (1.12)	3.80	Good
Control	1 – Sequences	3.12 (1.25)	2.50 (1.31)	2.81 (1.28)	2.81	Moderately Good
Control	2 – Loops	1.88 (1.25)	1.25 (1.16)	1.56 (1.21)	1.56	Weak
Control	3 – Conditionals	0.78 (0.99)	0.47 (0.81)	0.47 (0.81)	0.57	Weak
Control	Overall	1.93 (1.34)	1.41 (1.24)	1.62 (1.29)	1.65	Weak

Note: Efficiency scores are calculated using effective gameplay time, not total session duration. Sub-level scores were recorded for two task instances per concept; the values above are the mean of the two sub-level scores per concept per group. Control-group scores are computed across the full control group (n=8), following the effectiveness/efficiency/satisfaction scoring rule in Section III-C5 in which a non-completed task is scored 0; these scores therefore reflect both the performance of participants who progressed through a level and the zero scores of participants who did not reach it, and are the appropriate usability evidence for the group as assigned. The n=2 control-independent subgroup (participants who reached all three concepts unaided) is reported separately in Section IV-E for the learning-outcome comparison and is not the basis for this table. In the control group, the number of participants completing each level was 6 at Level 1, 4 at Level 2, 3 at Level 3, and 2 at each of Levels 4, 5, and 6, consistent with the per-participant stopping levels reported in Table VI.

As shown in Table V, the experimental group obtained an overall usability score of 3.80, which falls within the good band, whereas the control group obtained an overall score of 1.65, which falls within the Weak band. The experimental group scored in the good band for the Sequences (4.43) and Loops (3.80) concepts, declining to the Moderately Good band for the Conditionals concept (3.18). The control group, in contrast, scored in the Moderately Good band only for Sequences (2.81) and fell into the Weak band for both Loops (1.56) and Conditionals (0.57). This pattern indicates that usability declined with increasing programming-concept complexity in both groups, but that the decline was substantially steeper for the control group, which used the feature-reduced baseline version without the accessibility elements listed in Table I.

The same downward trend is observed across all three usability components. For the experimental group, effectiveness declined from 4.54 at Sequences to 3.29 at Conditionals, efficiency from 4.22 to 2.97, and satisfaction from 4.54 to 3.29. For the control group, the corresponding declines were steeper, with effectiveness falling from 3.12 to 0.78, efficiency from 2.50 to 0.47, and satisfaction from 2.81 to 0.47. Across all three components and all three concepts, the experimental group scored higher than the control group, consistent with the accessibility elements contributing to usability for low-vision children playing a block-based programming game.

Effective gameplay time, excluding pauses and check-ins, averaged 24 min 15 s for the experimental group and 16 min 52 s for the control group, out of an equal total session duration of approximately 28 min 40 s for both groups. The two groups therefore received effectively equal session time, but the control group spent proportionally more of that time in pauses, check-ins, and early termination, with active gameplay accounting for 58.9% of the session for the control group compared with 84.5% for the experimental group. Because the efficiency scores in Table V are computed from effective gameplay time rather than total session duration, this difference is reflected in the efficiency component but does not arise from unequal time allocation between groups.

D. Concept Exposure in the Control Group

Table VI shows, for the control group, whether each participant independently reached the levels covering all three core concepts within the session; this outcome is reported as a usability finding, not merely as a precondition for inclusion in the learning-gain analysis.

As shown in Table VI, only two of the eight control-group participants (25%) independently reached the levels covering all three core programming concepts within the session. The remaining six participants stopped at an earlier level: two stopped at Level 1, two at Level 2, one at Level 3, and one at Level 4, with no participant stopping at Level 5. The attrition was concentrated within the Sequences concept itself, where four of the eight participants stopped at Level 1 or Level 2 without progressing to the Loops concept. This concept-exposure outcome is reported here as a usability finding, since the proportion of control participants unable to reach a given concept directly quantifies the severity of the barriers present in the unadopted baseline environment and does so in a way that the group-mean usability scores in Table V, which average completed and non-completed tasks together, do not fully convey.

TABLE VI. CONTROL GROUP CONCEPT-EXPOSURE OUTCOMES

ID	Reached all 3 concepts?	Last level reached	Reason for non-completion
P06	Yes	Level 6 (Conditionals)	—
P14	Yes	Level 6 (Conditionals)	—
P02	No	Level 1 (Sequences)	Unable to place the first block using mouse drag-and-drop after multiple attempts; stopped interacting..
P04	No	Level 1 (Sequences)	Could not distinguish the low-contrast blocks from the background; repeated wrong selections
P08	No	Level 2 (Sequences)	Lost track of the block sequence without audio cues; five consecutive failed attempts, session ended early after check-in
P10	No	Level 2 (Sequences)	Unable to complete drag-and-drop placement of the second block; disengaged after repeated failed attempts
P12	No	Level 3 (Loops)	Could not select and connect the loop block with the mouse; five consecutive failed attempts; session ended early after check-in
P16	No	Level 4 (Loops)	Lost track of the required loop repetitions without audio feedback; stopped progressing after repeated incorrect placements
Total reaching full exposure: 2 / 8 (25%)			

Note: The last level reached, and the reason for non-completion for each participant were recorded from the session observation checklists and screen recordings referenced in Section III-C6. Reasons are reported as observed interaction behaviours (for example, inability to complete a drag-and-drop placement, or repeated wrong selections of low-contrast blocks) rather than inferred internal states.

E. Learning Outcome Results

Table VII reports individual-level pre-test and post-test scores for all experimental group participants and for control group participants who independently reached concept exposure.

As shown in Table VII, all eight experimental-group participants recorded a positive learning gain. For the experimental group, the pre-test mean was 1.75 and the post-test mean was 7.44, giving a mean gain of 5.69 (SD=0.53), with individual gains ranging from +5.0 to +6.5. No experimental-group participant recorded a gain below +5.0, indicating a consistent improvement across the group.

Because the control-independent subgroup comprises only two participants, fewer than the pre-registered threshold of three specified in Section III-D3, the corresponding group-level learning-gain comparison is omitted, and only the individual case data are reported for this subgroup. Participants P06 and P14 recorded gains of +2.5 and +2.0, respectively. Both gains are smaller than that of any experimental-group participant, and both participants began from a pre-test range (1.5 to 2.0) comparable to that of several experimental-group participants, such as P01 and P11 (pre-test 2.5).

TABLE VII. INDIVIDUAL PRE-TEST/POST-TEST SCORES

ID	Group	Pre-test	Post-test	Gain
P01	Experimental	2.5	8.0	+5.5
P03	Experimental	1.0	7.5	+6.5
P05	Experimental	3.0	9.0	+6.0
P07	Experimental	2.0	7.0	+5.0
P09	Experimental	1.5	6.5	+5.0
P11	Experimental	2.5	8.5	+6.0
P13	Experimental	0.5	6.0	+5.5
P15	Experimental	1.0	7.0	+6.0
P06	Control-independent	2.0	4.5	+2.5
P14	Control-independent	1.5	3.5	+2.0

Note: The control-independent subgroup is not representative of the control group as originally assigned, since it comprises only the two participants (of eight) who were able to independently reach concept exposure in the baseline environment. Any comparison drawn between this subgroup and the experimental group is therefore interpreted as a conservative estimate of the accessibility effect (Section III-D3): the six control-group participants who did not reach concept exposure are absent from this comparison entirely, and their exclusion is itself evidence of a barrier severity that a group-mean comparison would not capture.

F. Termination-Criterion Events

Table VIII summarises how often the proactive termination criteria described in Section III-C6 were triggered during testing, and their outcomes.

TABLE VIII. TERMINATION-CRITERION EVENTS BY GROUP

Group	"3 min no progress" triggers	"5 consecutive failed attempts" triggers	Continued after check-in	Took a break	Session ended early
Experimental	3	2	4	1	0
Control	11	9	2	3	9

As shown in Table VIII, the control group triggered a proactive check-in substantially more often than the experimental group, with 20 triggers in total compared with 5. The outcome of these check-ins also differed between the two groups. In the experimental group, most check-ins led to the session continuing: of the five check-in occasions, four led to continuation and one led to a break, and no experimental-group session ended early. In the control group, by contrast, the session ended early on 9 of the 14 check-in occasions. All trigger events were logged with a timestamp during testing; for example, participant P04 triggered the "3-minute no-progress" criterion at 00:08:42 into the session. These timestamps are retained in the raw observation records but are not reported individually.

G. Inter-Rater Reliability

Before formal scoring, both the primary rater and the second rater underwent a short calibration session: the raters independently scored a small set of practice responses drawn from the pilot testing phase (not included in the main analysis) and then compared their scores, discussing discrepancies until consensus was reached on the application of the scoring rubric described in Section III-D (one point per item, nine items in total). After this calibration, to assess scoring reliability, 30% of all pre-test and post-test responses (stratified by participant and by test occasion) were independently re-scored by the second rater, who remained blinded to group assignment and to the primary rater's scores. Inter-rater agreement calculated with Cohen's κ was 0.82, indicating almost perfect agreement (Landis & Koch, 1977), supporting the reliability of the scoring approach used for the primary rater's results reported in Table VII.

V. Discussion

A. Usability of the Accessible Version

The experimental group achieved a Good overall usability rating (3.80) for the accessible version, consistent with the range reported for accessible serious games for low vision children in prior work [3]. However, the score was not uniform across concepts: usability was Good for Sequences (4.43) and Loops (3.80) but declined to Moderately Good for Conditionals (3.18), and the same downward pattern was present in effectiveness, efficiency, and satisfaction scores alike. This suggests that the accessibility elements applied large, high-contrast screen design, adjustable colour and text, and audio feedback supported usability effectively for lower-complexity tasks, but that usability nonetheless degrades as programming-concept complexity increases, even when accessibility barriers related to screen design and multimedia are addressed. This is consistent with prior findings that screen design elements such as menus and buttons contribute directly to interface usability [10]. Because the accessibility package (Table I) remained constant across all levels while only task complexity varied, the within-group decline is more plausibly attributable to the cognitive demands of conditional logic itself than to a breakdown in the accessibility adaptations at higher complexity. This is a favourable finding relative to the interaction barrier reported for drag-and-drop block assembly in prior block-based programming accessibility work [5]: the accessible version, which incorporates a keyboard-based selection method alongside its other accessibility adaptations, appears to have kept the interaction itself usable across all three concepts, with the residual difficulty concentrated in the conceptual content rather than the input method. Because the present design varies screen design, multimedia, interaction method, and text simultaneously, this observation cannot isolate the specific contribution of the keyboard-based interaction component from the accessibility package.

B. Severity of Baseline Barriers and the Value of the Control Condition

Only two of the eight control-group participants (25%) reached concept exposure to all three programming concepts independently in the feature-reduced baseline version (Table VI); the remaining six stopped at some point between Level 1 and Level 4, with the attrition concentrated within the Sequences concept itself, where four of the eight participants stopped at Level 1 or Level 2. This is a substantially more severe barrier than the usability scores alone would suggest: the control-group overall usability score fell from Moderately Good for Sequences (2.81) to Weak for both Loops (1.56) and Conditionals (0.57), but because these scores are computed across all eight participants, including zero-scored non-completions, the numeric decline understates the practical severity captured in Table VI: a quarter of participants, not a numeric average, is arguably the more informative statistic for judging whether the baseline environment is usable at all for this population. The reasons for non-completion recorded in Table VI point to the interaction method and the screen design as the two most frequently observed points of difficulty: four of the six non-completing participants were recorded as unable to complete mouse-based drag-and-drop block placement, and the remaining difficulties involved distinguishing low-contrast blocks and losing track of the task without audio cues. Since both versions differ only in the accessibility elements listed in Table I (screen design, multimedia, interaction method, and text), and the control-group attrition is concentrated at the earliest levels while the experimental group performed well on the same concepts, the pattern is consistent with the removed accessibility package as a whole rather than the increase in conceptual complexity alone being the primary driver of the gap, since conceptual complexity was held constant between conditions. Because the accessible and baseline versions differ in multiple accessibility elements simultaneously (Table I), the specific contribution of the interaction method relative to the other adaptations cannot be isolated from the present design.

C. Learning Outcomes

All eight experimental-group participants showed a positive learning gain, ranging from +5.0 to +6.5 points (M=5.69, SD=0.53), a consistent pattern with no participant falling below the group's lower bound. The two control-independent participants who reached full concept exposure in the baseline version showed smaller gains (+2.5 and +2.0). As established in Section III-D3, this comparison must be read as a conservative estimate of the accessibility effect rather than a representative group comparison: it includes only the two control participants best positioned to learn from the baseline environment (Table VI), while the six control participants who did not reach concept exposure and who, by definition, had markedly lower learning opportunity are absent from the comparison entirely. The true

gap between the accessible and baseline conditions is therefore likely larger than the individual-level gain figures alone suggest.

Relating this to the usability findings in Section V-A, the experimental group's gains remained consistently high (≥+5.0) even for Conditionals, the concept at which usability had declined to Moderately Good rather than Good. This suggests that, within the accessible version, the residual usability decline observed for more complex concepts did not translate into a proportional decline in learning outcome: a Moderately Good usability level for a given concept still supported a learning gain comparable to concepts rated Good. This pattern would benefit from confirmation with a larger and more complexity-differentiated sample, given the descriptive nature of this dataset.

D. Design Tensions Between Playability and Accessibility

The termination-criterion event data provide indirect evidence of one such tension: keyboard navigation speed relative to task completion time. The experimental group's efficiency scores declined from 4.22 (Sequences) to 2.97 (Conditionals) even though effectiveness (task success) remained comparatively higher (4.54 to 3.29), a gap plausibly consistent with the keyboard-based selection method requiring more discrete key presses to construct increasingly complex block arrangements, trading interaction precision and accessibility for the raw speed of a direct drag-and-drop action; as with the other component-level observations in this study, this specific mechanism cannot be isolated from the accessibility package as a whole (Table I). This did not, however, translate into disengagement: experimental-group participants who triggered a proactive check-in continued the session in four of five instances, versus nine of fourteen check-in instances in the control group ending in early termination, suggesting that the accessible version's slower interaction pace was tolerated by children rather than experienced as frustrating enough to prompt withdrawal. This extends the accessibility model of [11] originally validated for a tap-to-select mathematics game to the specifically higher-friction case of block-based programming, indicating that the accessible version's design, including its keyboard-based interaction method, can preserve engagement even where it does not match the raw efficiency of unrestricted pointer-based interaction. A full account of the trade-off between audio feedback and game immersion, and between visual simplification and game attractiveness, requires the qualitative observation notes referenced in Section III-C6 and is not addressed by the quantitative data reported here.

E. Comparison with Prior Work

The overall effectiveness (3.91), efficiency (3.60), and satisfaction (3.91) scores obtained for the accessible version in this study are all lower than the corresponding scores reported for an accessible mathematics serious game for the same population (4.74, 4.55, and 4.92, respectively) [3]. Because both studies applied a broadly similar accessibility model, screen design, multimedia, and language adaptations derived from [11], this gap is more plausibly attributable to the additional interaction barrier specific to block-based programming than to a difference in the underlying accessibility approach: a mathematics game in which children select and tap an answer does not require the sequential, multi-step block construction demanded by sequences, loops, and conditionals, even when both interactions are mediated through an accessible, non-drag-and-drop input method. This is consistent with the distinction drawn in Section I between accessibility barriers that screen design and multimedia adaptations alone can resolve, and the interaction-specific barrier that block-based programming introduces regardless of those adaptations [20]. Relative to the fully non-visual, audio-based approach used for blind children in [5], the present results suggest that the accessible version's overall approach, preserving visual access through a keyboard-based interaction method combined with the other accessibility adaptations in Table I, rather than removing the visual channel entirely, is a viable middle path for the residual-vision case of low vision children, achieving Good overall usability despite the added interaction complexity of block-based programming. This is broadly consistent with assistive-technology approaches for mathematics learning among visually impaired populations, which similarly favour input methods that preserve residual vision where possible [28].

F. Limitations

This study has several limitations. First, the sample size (n=16, split into matched experimental and control groups of 8 participants each) is small; findings are reported descriptively and are not intended to support statistical generalisation. Second, participants were recruited from a single special education school; although experimental and control sessions were scheduled on separate days to minimise cross-group contamination, the sample reflects the specific educational and cultural context of that institution. Third, children with additional cognitive or motor impairments were excluded to reduce confounding, which limits the applicability of the findings to low vision children with co-occurring conditions. Fourth, although both groups received an equal fixed session duration, this does not imply an equal experience within that time: an experimental group participant who completed the core levels early spent the remainder of the session on non-core decorative activities, while a control group participant who struggled to progress may have spent most or all of the session attempting the first core level without success; this qualitative difference in what the time was spent on is a limitation of the equal-duration design. Fifth, the learning-gain comparison reported as individual case data in Table VII for the control-independent subgroup is subject to survivorship bias. Sixth, this study assessed learning gain immediately after the session; it does not assess retention of programming concepts over time. Seventh, beyond parental or guardian consent and the children's right to withdraw described in Section III-B, the study protocol did not include a separate, age-appropriate child assent procedure, nor did it specify formal data-protection arrangements for the screen and camera recordings collected during testing; both are noted here as procedural gaps that future replications of this design, particularly given the involvement of children with disabilities, should address explicitly.

VI. Conclusion and Future Work

In this study, a block-based programming serious game was designed for low-vision children aged seven years old, incorporating accessibility elements such as screen design, multimedia, and a keyboard-based interaction method in place

of the drag-and-drop interaction typically used in block-based programming environments. The prototype was refined through pilot testing and expert heuristic evaluation before user testing. Usability testing and a pre-test/post-test learning outcome assessment were conducted, benchmarked against a feature-reduced baseline version of the game. The accessible version achieved a Good overall usability score (3.80), compared to a Weak overall score (1.65) for the feature-reduced baseline version when computed across the full control group. Only 25% of control-group participants reached independent exposure to all three target concepts in the baseline environment, compared with 100% of experimental-group participants in the accessible version. Experimental-group participants showed a consistent learning gain (M=5.69, SD=0.53, range +5.0 to +6.5), descriptively larger than the gains observed for the two control-group participants who reached concept exposure independently (+2.5 and +2.0), a comparison interpreted conservatively due to survivorship bias in the control-independent subgroup. Accessibility elements such as screen design, multimedia, and interaction method are important in increasing the usability of block-based programming serious games for low vision children. Future research could extend this design to a larger, multi-site sample of low vision children, incorporate a delayed post-test to assess retention of programming concepts, and explore extending the accessibility model to children with additional visual or motor impairments, building on related efforts to extend computational-thinking tools to younger children [27] and to children with other developmental disabilities such as autism spectrum conditions [29].

ACKNOWLEDGMENT

The authors would like to express their sincere gratitude to Universiti Sains Malaysia for the invaluable support provided throughout the course of this research. This study would not have been possible without their encouragement and contributions.

DECLARATION ON GENERATIVE AI-ASSISTED TOOLS

Generative AI tools were used for language editing, formatting assistance, and organisation of the manuscript during preparation. The authors critically reviewed, edited, and approved the study design, data collection, analysis, interpretation, references, and final manuscript, and take full responsibility for the scientific content.

Hybridization of FA-YOLOv8 Model with Zebra Optimization Algorithm for Improving Traffic Light Detection and Tracking Under Low-Light Conditions

Adhwa Salemi, Muhammad Arif Mohamad*
Faculty of Computing, Universiti Malaysia Pahang Al-Sultan Abdullah, 26600 Pekan, Malaysia

***Abstract*—Traffic-light detection and tracking under low-light conditions remain difficult because signal heads can be small, dim, blurred, low in contrast, or affected by glare and reflections. This study develops a hybridization of Firefly Algorithm–You Only Look Once version 8 (FA-YOLOv8) with the Zebra Optimization Algorithm (ZOA) for offline analysis of recorded dashcam video under rainy, night-time, and cloudy conditions. YOLOv8 detects traffic-light candidates, FA performs attraction-based coordinate refinement and supports tracking continuity, and ZOA acts as an enhancement layer that adaptively searches FA control settings rather than replacing FA as the refinement mechanism. A controlled within-dataset comparison uses 300 real-world dashcam frames containing approximately 900 annotated traffic-light instances; the same annotated sequences support parameter adaptation and the baseline-versus-hybrid comparison, so the reported results characterize within-dataset behavior rather than held-out generalization. Compared with baseline FA-YOLOv8, MOTP increases from 31.84% to 37.59% under rainy conditions and from 49.47% to 72.50% under cloudy conditions. At night, Recall increases from 54.70% to 80.34% and F1-Score from 61.73% to 75.56%. Tracking continuity also improves in the reported point estimates: IDF1 rises from 72/90/85% to 82/94/90% for rainy/night/cloudy conditions, while identity switches fall from 95/18/45 to 48/8/22. These observations show that ZOA-based enhancement changes FA search behavior and is associated with improvements in several localization and identity-tracking measures within the evaluated sequences, although detection changes remain condition-dependent.**

Keywords*—*Traffic light detection; traffic light tracking; YOLOv8; firefly algorithm; zebra optimization algorithm; low-light conditions; adaptive parameter optimization; identity tracking

I. Introduction

Traffic-light perception requires reliable detection, localization, and tracking across consecutive road frames [1]. Under low-light conditions, weak contrast, glare, reflections, and rain blur can distort candidate locations and interrupt temporal continuity. These effects motivate a framework that can refine detected coordinates while adapting its search behavior to the illumination condition rather than relying on fixed optimization parameters.

The central problem addressed here is not simply low-light detection; it is the parameter sensitivity of FA when it is used to refine and track YOLOv8 detections. FA offers a useful attraction-based local search mechanism, but its convergence and exploration–exploitation behavior depend on control parameters [2]. A fixed configuration can therefore behave differently when the scene changes from cloudy to night-time or rainy conditions.

YOLOv8 is retained as the detection backbone and is not the main novelty of this study. The contribution lies in the optimization layer placed around the detector output: FA refines candidate coordinates, HSV analysis supports traffic-light state recognition, and ZOA adapts the FA control parameters to the current search difficulty.

Accordingly, the proposed method hybridizes FA-YOLOv8 with ZOA rather than replacing FA with another tracker. ZOA is introduced specifically as an enhancement layer for the existing FA-YOLOv8 framework: FA remains responsible for attraction-based coordinate refinement and temporal continuity, while ZOA searches the FA control settings, including the maximum generation setting and the parameters alpha, beta, and gamma. This complementary division targets FA parameter sensitivity while preserving the original refinement mechanism.

The contributions are fourfold. First, a FA-YOLOv8-ZOA hybridization is formulated for low-light traffic-light detection and tracking. Second, ZOA is used to enhance the existing FA-YOLOv8 framework through adaptive FA parameter search across rainy, night-time, and cloudy conditions. Third, the baseline FA-YOLOv8 and proposed hybrid are evaluated using detection/localization and identity-tracking metrics. Fourth, the analysis distinguishes condition-dependent changes and explicitly limits its conclusions to the offline, within-dataset experiment rather than claiming real-time deployment, independent generalization, or universal optimizer superiority.

II. Related Work

A. Low-Light Traffic-Light Perception

Low-light traffic-light detection is difficult because illumination changes simultaneously affect color, contrast, and object boundaries [3]. Deep detectors improve robustness over handcrafted methods, yet small and distant signals remain vulnerable to missed detections and unstable boxes when glare, rain reflections, or weak illumination suppress visual evidence [4]. These studies motivate robust perception, but they do not directly address the parameter sensitivity of an optimization-based refinement layer placed after detector output.

Tracking adds a temporal requirement: a correct detection must remain spatially stable and preserve its identity across frames [5]. Existing low-light tracking work commonly

*Corresponding author.

focuses on detector design, preprocessing, or tracking architecture [5], [6]. In contrast, the present study focuses on a narrower problem inherited from the baseline FA-YOLOv8 framework: how to enhance FA search behavior when fixed control settings become less suitable as illumination conditions change.

B. Firefly Algorithm as the Baseline Refinement Mechanism

The Firefly Algorithm (FA) is a swarm-based optimizer in which weaker candidate solutions move toward brighter, higher-fitness solutions [7]. Its attraction mechanism has previously been applied to object tracking [8]. In the baseline FA-YOLOv8 framework, this behavior is used to refine detected traffic-light coordinates and support continuity across frames [9]. The main limitation relevant to this study is not the absence of a refinement mechanism, but the sensitivity of FA convergence and search behavior to fixed control settings.

In the baseline FA-YOLOv8 formulation used in this study, each firefly represents a candidate traffic-light coordinate, and its brightness represents the quality of that candidate [9]. The implemented light-intensity relationship is expressed as:

$$I_i = I_0 e^{(-\gamma * fitness_i)} \quad (1)$$

where, I_i is the updated light intensity of candidate i, I_0 is the initial intensity, γ is the light-absorption coefficient, and $fitness_i$ represents the candidate quality. A weaker candidate moves toward a stronger candidate using the implemented update:

$$x_i(t+1) = x_i(t) + \beta\left[x_j(t) - x_i(t)\right] + \alpha * L() \quad (2)$$

where, alpha controls randomized step size, beta controls attraction toward the better candidate, and L() denotes the stochastic Lévy-flight component used in the implementation. The process iterates until the termination criterion is met and the best coordinate is returned. These parameters are effective only when appropriately tuned; static settings can be suboptimal when the illumination condition changes [10].

C. Zebra Optimization Algorithm for FA Parameter Adaptation

ZOA models zebra foraging and defensive behavior through complementary search phases [11]. In this work, ZOA is not used as an independent replacement for FA and is not treated as a competing tracker. Instead, it is embedded as an enhancement mechanism that searches FA control settings and retains settings that improve the implemented FA fitness. This design is consistent with the thesis objective of improving the existing FA-YOLOv8 framework rather than replacing its attraction-based refinement stage.

This role separation defines the hybridization studied here: FA performs localized coordinate refinement, whereas ZOA modifies how FA searches by adapting its control settings [12]. Prior work establishes the individual usefulness of FA and ZOA, but does not directly address this specific use of ZOA as a parameter-enhancement layer for FA-YOLOv8 in low-light traffic-light tracking. The proposed design therefore targets parameter sensitivity in the baseline framework without changing the YOLOv8 detector itself.

III. Proposed Hybridization of FA-YOLOv8 with ZOA

As illustrated in Fig. 1, the processing pipeline begins with prerecorded dashcam frames and YOLOv8 candidate detections. HSV-based pixel analysis supports traffic-light state recognition, after which FA refines candidate coordinates. For each processed frame containing traffic-light candidates, the baseline FA configuration is evaluated first, ZOA searches alternative FA control settings, and the selected settings are used for the final FA refinement pass. The refined detections are then evaluated using detection, localization, and identity-tracking measures. Thus, the adaptive feedback shown in Fig. 1 is applied during offline frame processing rather than as a once-per-sequence global tuning stage.

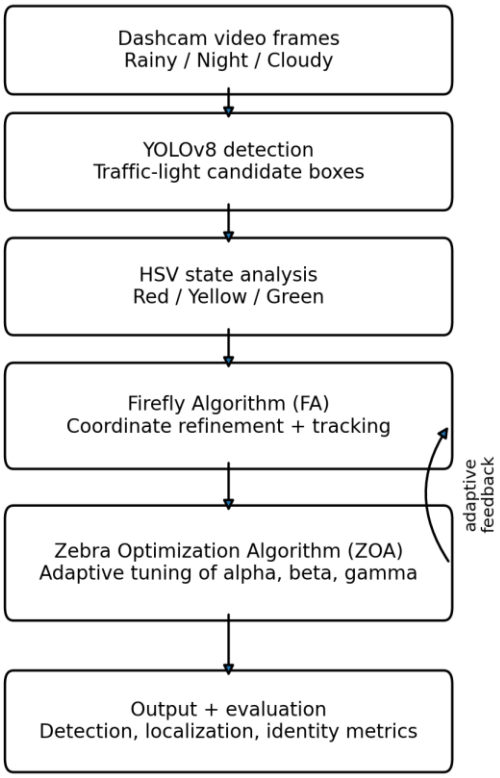

Fig. 1. Processing flow of the proposed FA-YOLOv8-ZOA hybridization.

A. YOLOv8 Detection and HSV State Analysis

YOLOv8 is responsible for candidate localization, class prediction, and confidence information. HSV analysis is used within the detected region to help distinguish the red, yellow, and green traffic-light states. The metaheuristic stages operate on the detected candidates; they do not replace YOLOv8 feature extraction or class prediction.

B. FA Coordinate Refinement and ZOA Parameter Adaptation

FA begins with candidate positions derived from the detector output. Candidate fitness is evaluated, brightness is updated, and weaker fireflies move toward better candidates according to the attraction and stochastic movement terms in Eq. (1) and (2). ZOA operates at the parameter level: candidate settings are sampled within the implementation bounds, evaluated by running FA, and retained when the resulting FA

fitness improves. The selected settings are then returned to FA for the final coordinate-refinement pass. This preserves FA as the refinement mechanism while using ZOA only to enhance its search configuration.

Operationally, the implementation searches a parameter vector containing maximum generations together with alpha, beta, and gamma. The implemented fitness is F = max(0, N - 0.1D), where N is the number of traffic-light candidates, and D is the sum of pairwise Euclidean distances among candidate centers. The optimizer therefore favors configurations that preserve candidate count while reducing spatial dispersion; Precision, Recall, F1-Score, IDF1, and IDSW are evaluation measures reported after processing rather than weighted terms inside the ZOA fitness function. The implementation searches max generation in [50, 200], alpha in [0.1, 0.5], beta in [0.5, 2.0], and gamma in [0.1, 1.0]. The archived code uses a ZOA population size of 1 and one ZOA update iteration per processed frame. The baseline FA initialization uses five fireflies with max generation = 100, alpha = 0.2, beta = 1.0, and gamma = 0.2. These implementation details define the parameter-enhancement mechanism evaluated in this study.

IV. Experimental Setup

A. Dataset and Selection Criteria

The experimental evaluation uses prerecorded real-world traffic-light video captured with a vehicle-mounted dashcam and processed offline. The data contain 300 selected frames and approximately 900 annotated traffic-light instances, divided equally across rainy, night-time, and cloudy conditions, as summarized in Table I. The same annotated sequences are used as feedback during ZOA adaptation of the existing FA-YOLOv8 outputs and for the subsequent baseline-versus-hybrid measurements; YOLOv8 is not retrained during ZOA adaptation. Accordingly, this study is a controlled within-dataset comparative evaluation of the incremental effect of adding ZOA-based enhancement to FA-YOLOv8 rather than an independent held-out generalization experiment. Because this study evaluates offline recorded video, online throughput, FPS, and embedded real-time deployment are not defined as primary experimental objectives.

TABLE I. Dataset Distribution Under Selected Low-Light Conditions

Condition	Frames	Annotated TLs	Primary Challenge
Rainy	100	300	Reflection and rain blur
Night	100	300	Low illumination
Cloudy	100	300	Inconsistent lighting
Total	300	900	Controlled within-dataset comparison

The dataset was filtered according to the predefined selection criteria summarized in Table I: traffic lights had to be visible from a direct frontal view, motion blur had to remain limited, object size had to be detectable, and severely overexposed, extremely dark, fully occluded, or excessively blurred cases were excluded. These criteria define the controlled scope of the reported results and should be considered when interpreting performance outside the evaluated low-light scenes.

B. Evaluation Metrics

Performance is evaluated with MOTP, Precision, Recall, and F1-Score to describe detection and localization behavior. Because the proposed method also targets temporal continuity, the analysis includes IDF1, IDSW, Mostly Tracked (MT), Partially Tracked (PT), and Mostly Lost (ML). These metrics are used to compare the same baseline and enhanced framework under the three conditions listed in Table I.

The principal experimental control is baseline FA-YOLOv8 versus the proposed FA-YOLOv8-ZOA framework because the research objective is to determine the incremental effect of using ZOA to enhance the previously developed FA-YOLOv8 model. The broader study also contains supporting comparisons with other optimization-based YOLOv8 variants, but the present article does not make a universal claim that ZOA is superior to every possible parameter-search strategy. Its central question is whether the addition of ZOA-based parameter enhancement changes the performance of FA-YOLOv8 under the tested low-light conditions.

V. Results and Discussion

A. Adaptive FA Parameter Behavior

Table II shows that ZOA returns different mean FA parameter values for the three illumination conditions, supporting the premise that one fixed FA configuration is not equally suitable for every scene type. Rainy conditions require the largest mean maximum generation, while the night-time subset uses a lower mean alpha and a higher mean gamma. These differences indicate condition-dependent search behavior rather than a single global parameter setting.

TABLE II. Mean Adaptive FA Parameters Generated By ZOA

Condition	Max Gen	α	β	γ
Rainy	155.83	0.25	1.56	0.47
Night	139.08	0.15	1.42	0.59
Cloudy	125.25	0.21	1.33	0.33

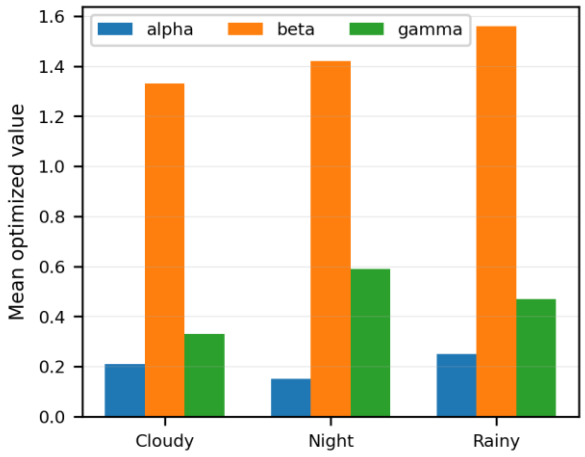

Fig. 2. Mean FA parameter values produced by adaptive ZOA tuning.

The parameter analysis in Table II and Fig. 2 provides mechanism-level evidence for the proposed hybridization. In

baseline FA-YOLOv8, the control settings are relatively static, whereas the hybrid framework changes them through ZOA. Within the tested data, this enhancement is associated with condition-dependent FA search behavior and changes in localization and tracking continuity.

B. Detection and Localization Results

As shown in Table III, under rainy conditions, MOTP increases from 31.84% to 37.59%, while Precision increases from 73.94% to 100%. Recall decreases from 25.45% to 22.92% and F1-Score decreases slightly from 37.83% to 37.29%. The 100% Precision value should therefore not be interpreted as perfect overall detection: it occurs together with low Recall, indicating a conservative operating point in which the reported detections contain no counted false positives while a substantial proportion of annotated traffic lights remain undetected. The rainy result therefore indicates improved localization precision and fewer false detections, but not a uniform improvement in detection completeness.

TABLE III. DETECTION AND LOCALIZATION RESULTS

Metrics	Conditions (FA-YOLOv8)			Conditions (Hybrid)		
	Rainy	Night	Cloudy	Rainy	Night	Cloudy
MOTP (%)	31.84	32.84	49.47	37.59	39.74	72.50
Precision (%)	73.94	71.11	100.00	100.00	71.21	100.00
Recall (%)	25.45	54.70	25.57	22.92	80.34	35.25
F1-Score (%)	37.83	61.73	40.72	37.29	75.56	52.15

The night-time results in Table III show a different pattern. MOTP increases from 32.84% to 39.74%; Recall rises from 54.70% to 80.34%; and F1-Score rises from 61.73% to 75.56%, while Precision remains nearly unchanged at 71.11% versus 71.21%. These changes indicate stronger detection completeness together with improved localization behavior under night-time illumination.

Cloudy scenes in Table III provide the strongest localization gain: MOTP increases from 49.47% to 72.50%, Recall rises from 25.57% to 35.25%, and F1-Score increases from 40.72% to 52.15%, while Precision remains at 100%. As in the rainy result, 100% Precision should be read together with the relatively low Recall rather than as evidence of perfect detection. Across the three conditions, the results show improvements in several, but not all, detection and localization measures.

C. Tracking Continuity and Identity Consistency

Table IV and Fig. 3 show that identity continuity improves in the reported point estimates for all three evaluated environments. IDF1 increases from 72% to 82% in rain, 90% to 94% at night, and 85% to 90% in cloudy scenes. Identity switches fall from 95 to 48, 18 to 8, and 45 to 22, respectively. MT also increases, while ML decreases across all three conditions.

These tracking results form the clearest observed pattern in the current experiment: after ZOA-based enhancement, the reported sequences show fewer identity switches and higher IDF1. They complement the detection metrics because temporal association can improve even when a frame-level metric such as Recall or F1-Score does not improve. The interpretation is restricted to the evaluated runs and does not claim statistical variability across repeated stochastic trials.

TABLE IV. TRACKING AND IDENTITY CONSISTENCY RESULTS

Conditions	IDF1 (%)	IDSW	MT (%)	PT (%)	ML (%)
Rainy	72 -> 82	95 -> 48	45 -> 58	40 -> 34	15 -> 8
Night	90 -> 94	18 -> 8	80 -> 88	18 -> 11	2 -> 1
Cloudy	85 -> 90	45 -> 22	65 -> 74	30 -> 23	5 -> 3

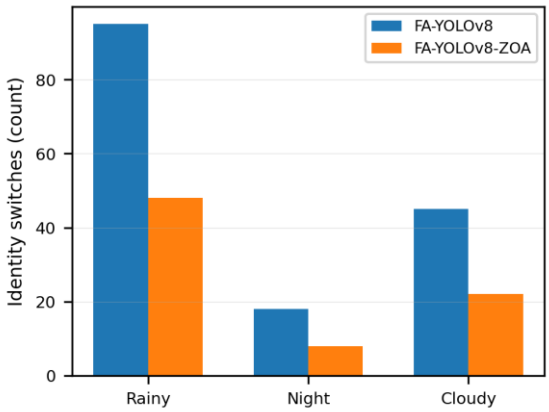

Fig. 3. Reduction in identity switches after YOLOv8 was hybridized with ZOA.

D. Qualitative Detection and Tracking Behaviour

The representative outputs in Fig. 4 are consistent with the quantitative observations. Baseline FA-YOLOv8 detects traffic-light candidates in all three environments but shows moderate coordinate and continuity stability in difficult frames. After ZOA-based parameter enhancement is introduced, the illustrated outputs show more stable localization and stronger identity preservation, particularly under night-time and cloudy illumination.

Fig. 4. Representative inputs, baseline FA-YOLOv8 outputs, and proposed FA-YOLOv8-ZOA outputs for cloudy, night, and rainy scenes.

E. Extension Beyond the Baseline FA-YOLOv8 Study

This work extends the previously published FA-YOLOv8 framework [2]. The earlier study established the feasibility of combining FA with YOLOv8 for traffic-light detection; the present study adds ZOA as an enhancement layer for adaptive FA parameter search, condition-specific parameter analysis, and a broader evaluation of localization and identity continuity [13].

Unlike approaches that primarily modify detector architecture, enhancement preprocessing, or multi-camera fusion [1], [2], the proposed contribution operates at the optimization/refinement stage. Its purpose is not to replace FA, but to enhance how the FA component searches and refines coordinates after YOLOv8 has produced candidate detections.

VI. Conclusion

This study hybridizes FA-YOLOv8 with the Zebra Optimization Algorithm as an enhancement mechanism for offline traffic-light detection and tracking under selected low-light conditions. YOLOv8 supplies candidate detections, FA remains responsible for attraction-based localization refinement, and ZOA searches FA control settings to adapt the refinement behavior to illumination-dependent difficulty.

Within the controlled same-sequence comparison, the hybrid shows favorable changes in several localization and tracking point estimates. Rainy MOTP and Precision increase, cloudy MOTP increases substantially, night-time Recall and F1-Score improve, and the reported identity metrics show higher IDF1 and fewer identity switches in all three tested conditions. At the same time, rainy Recall and F1-Score do not improve, and the 100% Precision cases coexist with low Recall. These findings therefore support a narrower conclusion: ZOA-based enhancement modifies FA search behavior and is associated with improvements in selected metrics within the evaluated offline sequences; they do not establish real-time deployment performance, universal optimizer superiority, or independent generalization to unseen traffic scenes.

Future work should follow the constraints already identified in this study by expanding the dataset to more diverse intersections, camera viewpoints, and more severe visibility conditions such as fog, heavy rain, extreme glare, tunnel exits, overexposure, and stronger occlusion. If the framework is later adapted for online or vehicle-based deployment, computational efficiency, hardware-specific runtime, and embedded implementation should then be evaluated explicitly. Additional road-object classes and broader traffic-scene coverage can also be investigated without changing the central role of ZOA as an enhancement to FA-YOLOv8.

Enhanced Explainable Multi-Agent Generative Artificial Intelligence Framework for Personalized Education

Hesham M. A. Abdullah[1], Elham Alzain[2]*
Al-Fayha Private College, Jubail, Saudi Arabia[1]
Applied College, King Faisal University, Al-Ahsa, 31982, Saudi Arabia[2]

***Abstract*—Generative Artificial Intelligence (GenAI) and Large Language Models (LLMs) have enabled personalized education via intelligent tutoring, adaptive learning, automated assessments, and personalized feedback. Nevertheless, educational AI systems are still confronted with challenges, including high computational complexity, long inference time, unreliable content generation, limited explainability, and ineffective multi-agent orchestration. To this end, this study proposes LITE-Trust, a Lightweight Trust-Aware Explainable Multi-Agent Generative Artificial Intelligence Framework for personalized education, which consists of learner profiling, Knowledge State Estimation (KSE), the Educational Library and Readers Optimization (ELRA) algorithm, relevance-based selective agent orchestration, trust evaluation, and an Explainability Engine. The ELRA algorithm is applied to optimize learner-specific educational configurations by taking learning requirements, trust, and computational efficiency into account, and selective orchestration is conducted to reduce computational overhead by only activating relevant agents. Experiments on the EdNet and Open University Learning Analytics Dataset (OULAD) demonstrate that LITE-Trust achieves 10.5/9.5ms latency, 80.5/81.3 MB memory, and 1.92 M parameters, which is computationally more efficient than the compared methods. In addition, LITE-Trust attains 95.0%/94.6% fidelity, 94.1%/93.4% explanation quality, and 92.6%/92.1% interpretability on the two datasets. Besides, the ELRA algorithm significantly outperforms existing algorithms in terms of various metrics. Overall, the experimental results verify that LITE-Trust can effectively balance personalization, learning quality, trust, explainability, and computational efficiency, thereby facilitating the practical application of lightweight and trustworthy GenAI systems in personalized education.**

I. Introduction

Artificial Intelligence in Education (AIED) has evolved from rule-based educational systems into Intelligent Tutoring Systems (ITSs), personalized learning, Generative AI, and LLMs [1, 2]. These advances allow the creation of content, recommendations, and feedback and offer tutoring services to learners individually or in groups. Still, the growing complexity of AIED and the use of large-scale models and many agents have made education-related artificial intelligence challenging to develop and control.

Current educational AI systems suffer from several limitations. Large-scale transformer-based models increase the computational complexity, memory consumption, inference time, and cost of deploying these systems. Multi-agent educational systems execute multiple agents without considering relevance to the current educational context, thus introducing unnecessary costs [3]. In addition, educational tutoring systems currently lack reliable mechanisms to assess trust and hallucination, potentially propagating unsubstantiated or factually incorrect information to the learner. Finally, these systems have limited explainability, as neither the learners nor instructors are often privy to the decision-making process of the AI. Most importantly, existing optimization methods are typically single-point, only considering one optimization criterion (e.g., prediction accuracy or learning path optimization) rather than jointly optimizing prediction, learning path adaptation, trust, explainability, agent coordination, and computational cost.

These limitations motivate this work by highlighting several research challenges, including single-agent, static multi-agent, limited trust-aware optimization, insufficient explainability, high computational cost, the absence of lightweight educational AI, and limited educational optimization. Table I explains the comparison of proposed and existing approaches.

TABLE I. Comparison of Existing Approaches and LITE-Trust

Methods	Personalization	Multi-Agent	Trust	XAI	Lightweight	Optimization
Existing method	✓	Partial	✗	Partial	✗	Partial
LITE-Trust	✓	✓	✓	✓	✓	✓

The proposed LITE-Trust is a lightweight multi-agent educational AI framework that comprises 1) learner profiling, 2) KSE, 3) ELRA, 4) dynamic agent orchestration, 5) trust evaluation, and 6) explainability. The ELRA optimizes learner-specific educational configurations while relevance-based pruning minimizes unnecessary agent execution. On the other hand, trust evaluation enhances the credibility of produced

*Corresponding author.

educational content, and the explainability engine offers learner-specific rationales. The major contributions include the following:

- A lightweight multi-agent educational AI framework that incorporates personalization, optimization, trust, and explainability features.
- The ELRA algorithm for personalized education optimization.
- A trust-aware evaluation method for enhancing the reliability of generated educational content.
- An explainability engine that enables transparent personalization decisions.
- A dynamic agent orchestration technique that minimizes computational overhead while maximizing the accuracy of personalization.
- A comprehensive evaluation of the performance in terms of learning, trust, explainability, optimization, and computational efficiency.

The rest of this study is structured as follows: Section II describes the related work. Section III presents the LITE-Trust framework. Subsequently, Section IV provides an experimental analysis and discussion. Finally, Section V concludes this study and identifies limitations and future directions.

II. Related Works

A. AI and Generative AI in Education

AI and Generative AI methods efficiently enhance collaborative learning, AI-enabled teaching, and lesson preparation in educational systems. The following presents a survey of AI and Generative AI in educational systems. Alyoussef et al. [4] and Algerafi et al. [5] present a technology acceptance model-based AI adoption architecture for cooperative learning. The system incorporates perceived accessibility, recognized usefulness, engagement factors, and trust attitude to evaluate AI adoption. To evaluate the relationships between these factors, this the study uses structural equation modeling. The system enhances students' behavioural intention and AI-supported technologies in learning environments. Oh et al. (2025) present the AI-based MATH41 system for mathematics teacher education. This approach is employed for generating teaching materials for students and teaching with the aid of Generative AI and MATH41 methods. Here, the learning materials are prepared by the system, which helps to enhance lesson planning skills and AI-enabled learning.

Overall, the discussed research highlights the potential of using AI and GenAI for enhancing engagement, adoption, and content development; however, they are focused on different aspects of using these technologies. The adoption-centric studies explore behavioural and psychological aspects, while GenAI research mainly concentrates on content and teaching materials. Hence, there is a gap in the studies, which implies the need for further investigations. Specifically, there is a need for studies exploring ways of combining learner state adaptation and using GenAI for generating decisions with high computational efficiency and reliability.

B. Personalized and Adaptive Learning

Personalized and dynamic learning methods utilized AI to analyze learners' knowledge, ability, and learning process to provide customized learning content, dynamic assessments, and personalized learning pathways. These methods effectively improve learner participation, learning efficacy, and academic excellence. The following section presents a survey of personalized and responsive learning works. Pradeesh et al. (2025) present an AI-supported personalized learning method by employing a knowledge-centric concept assessment. The subsystem incorporates retrieval-augmented generation, exercise-aware knowledge tracing, and Generative AI to analyze students' knowledge deficiencies, generate responsive evaluations, and provide personalized recommendations. Therefore, this research enhances learning outputs using concept-level assessments. Ma et al. [8] introduce an AI-based adaptive language learning system that consolidates natural language processing and a recurrent neural network to generate personalized learning approaches. The component analyses students' linguistic proficiency, speech patterns, and grammar to provide dynamic learning content, deliver real-time feedback, and recommend adaptive learning pathways. Thus, this research enhances student participation and English proficiency. Lou et al. [9] present an adaptive educational path-planning methodology that implements reinforcement learning and a cognitive graph to produce personalized learning paths. The subsystem continuously monitors learners' cognitive states, evaluates learning performance, and enhances content sequencing using predictive analytics. Thus, the presented system improves learning efficiency and educational outputs.

These approaches realize personalization based on knowledge tracing, learner proficiency analysis, and reinforcement-optimized path selection. Nevertheless, most of the proposed approaches concentrate on content adaptation and path personalization, while trustworthiness, explainability, and computational efficiency are insufficiently considered, which emphasizes the necessity of the developed approach, which is based on learner knowledge trace personalization.

C. Multi-Agent Systems in Education

Multi-Agent Systems (MAS) enable academic applications by allocating learning, tutoring, recommending, and assessment functions among several agents. Viswanathan et al. (2022) introduce a multi-agent learning system that coordinates multiple agents of personalized educational activities. Chang et al. [11] suggested a multi-agent approach to personalize education by dividing educational tasks among several agents. Rida et al. (2025) attempted to perform a multi-agent approach to achieving personalized educational services by assigning educational tasks to cooperating agents. Overall, the authors demonstrated that multi-agent approaches could be applied to perform specialized tasks, specifically in education. However, the majority of the works above employed a multi-agent approach without jointly considering trust evaluation, explainability, computational simplicity, and optimization, which limits adaptive and personalized learning by requiring extra agents to perform learning tasks, thus imposing

substantial overhead. As such, there is a need to develop a lightweight multi-agent architecture that targets accomplishing educational tasks while incorporating trust evaluation and explainability to ensure high-quality personalized learning.

D. Trustworthy and Explainable AI in Education

Trustworthy and explainable AI is necessary in education to confirm that AI-enabled decisions are transparent, responsible, explainable, and dependable for students and teachers. Latest studies focus on developing trustworthy governance, interpretable academic performance prediction, and reliable knowledge tracking strategies. The following is a survey of trustworthy and explainable AI in education. Evangelista et al. [13] introduce an innovative approach to a policy-as-code system that ensures trustworthy AI management in higher education. The component tracks institutional requirements and converts them into computable policies and uses a gatekeeper to evaluate system performance, calibration, fairness, explainability, and system limits. It additionally integrates fairness mitigation, SHapley Additive exPlanations (SHAP)-based interpretability, uncertainty-aware decisions, and tamper-evident audit procedures. Hence, the system allows explainable, accountable, and implementable AI governance during the development and deployment process. Raji et al. [14] introduce an explainable Machine Learning (ML) method to forecast the Deaf and Hard of Hearing learners' performance. The study deployed ML methods with Local Interpretable Model-agnostic Explanations (LIME) and SHAP to explain the forecasting results and detect important academic performance features. The combination of eXtreme Gradient Boosting (XGBoost), ExtraTrees, and Random Forest models resulted in 92.99% accuracy. Lu et al. (2024) proposed a trustworthy knowledge tracking model for an AI-enabled tutor system. Then, proposed three-level solutions to improve transparency, accountability, and interpretability through the integration of AI explanation techniques with educational systems. In turn, technical explanations are transformed into natural learning outcomes and presented through the ITS interface. Experimental evaluation shows that the presented model enhanced students' and teachers' trust and knowledge of the system.

These works relate to trustworthiness at various levels, from governance to prediction explainability and knowledge tracking. Yet, the emphasis is on providing an appropriate explanation or validation of each AI-based decision. These studies do not consider the combined evaluation of trust in the system with optimization of individual decisions and coordinated adaptation of agents. Consequently, it appears that the development of an integrated approach for a trustworthy, explainable, and learner-based system is needed.

E. Lightweight AI for Educational Applications

Lightweight AI models have emerged as capable approaches for educational applications, which enable real-time learner assessment while requiring lower computational resources. The following is a survey of lightweight AI for educational applications. Radharani et al. [16] present a light attention-based framework for detecting student attentiveness based on their facial expressions. MobileNet, together with channel and spatial attention, is deployed to identify facial features such as eye closure, mouth movements, and gaze. It achieves 91.2% accuracy with fewer parameters, which supports real-time classroom deployment [17]. Yu et al. (2025) present an IoT and edge-assisted system for computer-assisted learning. Here, IoT sensors are employed to record the engagement level of the students, while the edge devices process the data locally to provide immediate feedback with the aid of a lightweight stacked Long Short-Term Memory (LSTM) model. The system provides students with real-time feedback with 99.3% accuracy. Qorich et al. [18] introduce a context-based AI-enabled question generation approach for academic assessment that employs a lightweight transformer model. The subsystem combines a Convolutional Neural Network (CNN) module with a Bidirectional and Auto-Regressive Transformer (BART) base to enhance context-aware representation while preserving lower computational complexity; hence, this framework is suitable for a real-time educational environment.

These studies reduce computational costs by utilizing edge processing and lightweight transformers while ensuring effective educational outcomes. However, the efficiency is demonstrated in individual components, while the system-level factors, including agent execution, optimization, and trustworthiness, are limited [19]. Thus, more attention should be dedicated to developing educational frameworks that guarantee efficient model and end-to-end systems.

F. Metaheuristic Optimization for AI-Based Education

Optimization strategies employed in AI-powered learning include the use of heuristic search and evolutionary algorithms in optimizing learning pathways, content sequencing, learner modelling, and academic decision support. Most of the existing works used optimization algorithms like Ant Colony Optimization (ACO), Genetic Algorithm (GA), Particle Swarm Optimization (PSO), and Library and Readers Algorithm (LRA) [22]. These algorithms enhance optimize learning approaches, educational assessment, quality of recommendations, and adaptive educational processes by identifying optimal solutions under multiple learning objectives. Subsequently, they enhance personalization, learner participation, and overall educational performance. However, most previous optimization methods mainly focus on optimizing individual educational tasks while needing iterative optimization and parameter tuning, which improves computational overhead and execution time. Furthermore, they provide limited support for lightweight multi-agent coordination, trust-based education content assessment, interpretable AI recommendations, dynamic prompt optimization, and computationally effective personalized learning [23]. The abovementioned limitations emphasize the requirement for an integrated optimization system capable of balancing personalization, trustworthiness, transparency, and computational efficiency in AI-driven educational technologies.

G. Research Gap and Positioning of the Proposed Framework

The literature review demonstrates that previous AI-enabled personalized learning systems have intelligent learner profiling, advanced tutoring, content recommendation, and

learning path generation. However, they do not adequately address high computational overhead, ineffective trust evaluation, static multi-agent coordination, limited explainable recommendations, and optimization methods that mainly focus on individual educational tasks instead of an integrated learning system [24]. Furthermore, recent methods offer limited optimization of AI agent selection, learning path adaptation, prompt generation, trust analysis, and computational resource allocation simultaneously, which reduces their practical deployment and scalability in resource-limited educational environments.

To address these challenges, the presented LITE-Trust system designs a lightweight trust-aware explainable multi-agent generative AI architecture optimized using the presented ELRA algorithm. In contrast to existing approaches, ELRA automatically coordinates educational agents, executes trust-based optimization, adapts personalized learning pathways, optimizes prompt selection, and minimizes computational complexity while integrating explainability and academic integrity assessment. Subsequently, the presented system positions itself as a unified, lightweight, trustworthy, and computationally effective approach for advanced AI-assisted personalized learning.

For the purpose of comparison, the capabilities in Table II are classified according to their explicit implementation in the reviewed studies. A ✓ indicates that the capability is directly implemented as a core component, ✗ indicates that it is not obviously addressed, and Partial indicates that the capability is considered indirectly or to a limited extent. The classification is based on the methods and objectives reported in the corresponding studies instead of inferred from their application context. Table II indicates that most of the studied works address some specific capabilities rather than the combination of their implementation. Personalization and optimization are the most commonly performed capabilities. Some papers address the coordination of multi-agent systems, but it is not fully explored, and only a few works mention multi-agent coordination, trust evaluation, XAI, and lightweight processing. In contrast, the LITE-Trust system combines several capabilities, which are partially addressed in the existing solutions, namely KSE-based personalization, ELRA optimization, dynamic multi-agent coordination, trust evaluation, XAI, and lightweight. However, it should not be assumed that other systems do not possess the mentioned capabilities.

III. PROPOSED LITE-TRUST FRAMEWORK

A. Overall Architecture

The presented LITE-Trust framework initially collects learner information, including demographic characteristics, academic history, prior knowledge, learning preferences, assessment performance, engagement patterns, and interaction logs, to construct a dynamic learner profile as shown in Fig. 1.

The KSE subsystem then analyzes the obtained profile to estimate learners' competency levels and identify learning gaps. These outputs are then processed by the proposed ELRA, which identifies candidate educational policies, evaluates trust-aware recommendations, and optimizes educational decisions through personalized enhancement. Based on the optimized strategy, the lightweight multi-agent collaboration module adaptively activates and collaborates with the most suitable educational agents, which include the tutor, assessment,

feedback, recommendation, and academic integrity agents, based on the current learning context. Then, the explainability component analyzes the produced recommendations to provide transparent educational justifications, while the academic integrity module analyzes responsible AI usage, originality, critical thinking, and authentic learning behaviour. Finally, personalized learning recommendations are offered to learners, and continuous learner interactions are used to update learner profiles and knowledge state estimation, which enables adaptive, trustworthy, explainable, and computationally effective AI-enabled personalized learning.

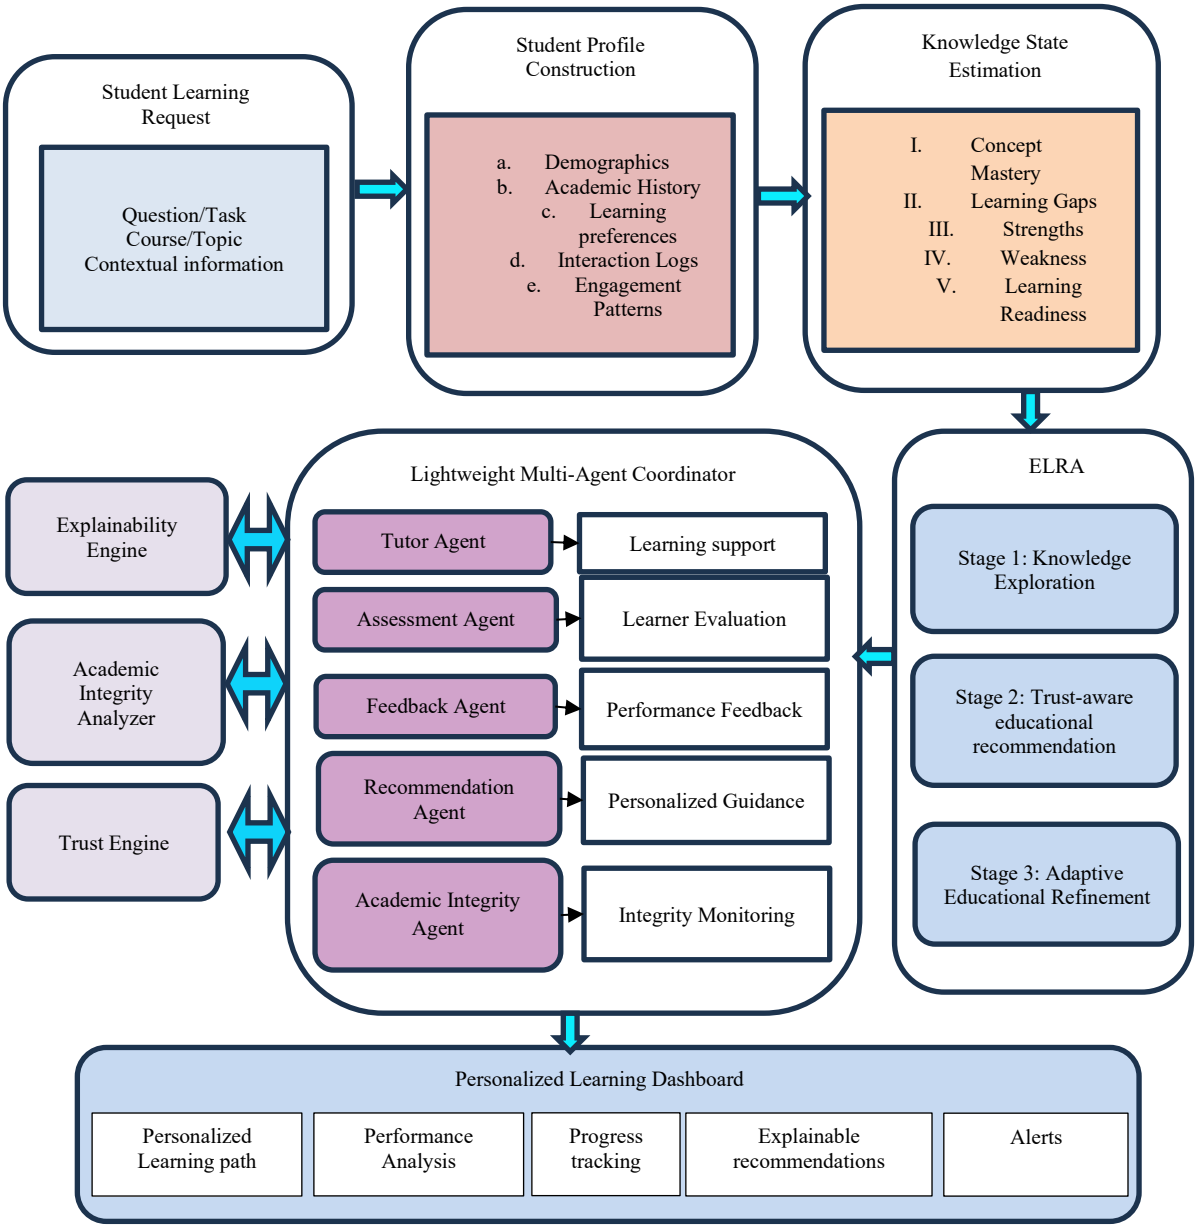

Fig. 1. Overall architecture of the LITE-Trust framework.

B. Student Profile Construction Modules

The student profile construction subsystem establishes a dynamic and comprehensive learner profile, supporting personalized educational decision-making within the LITE-Trust system. Previous AI-enabled learning systems often depend on static learner profiles or limited educational indicators, which makes it difficult to extract learners' developing knowledge, engagement, behavioural patterns, and individual learning preferences, which frequently leads to ineffective personalisation. To resolve the existing shortcomings, the proposed module combines heterogeneous learner data, which includes demographic characteristics (D_i), prior knowledge (P_{ki}), academic history (A_{Hi}), learning preferences (L_{Pri}), engagement patterns (E_{Pi}), assessment performance (A_{Pi}), and interaction logs (I_{Li}), into a unified learner profile that is continuously updated throughout the learning process. The learner profile is defined as,

$$LP_i = D_i, P_{ki}, A_{Hi}, L_{Pri}, E_{Pi}, A_{Pi}, I_{Li} \quad (1)$$

where, LP_i represents the learner profile. This representation consolidates multiple learner competencies into a unified learner profile, which provides a more holistic representation of learner competency than strategies that depend on limited academic indicators. The profile is continuously updated to reflect changes in the learner's progress, which is denoted as,

$$LP_i^{(t+1)} = LP_i^{(t)} \oplus L'_i \quad (2)$$

where, $LP_i^{(t)}$ represents the current learner profile, L'_i represents the newly produced learning evidence, and $\oplus$ represents the profile update operation. The newly obtained learning evidence consists of the assessment outcomes, engagement activities, and interaction records. Mathematically, the given formulation enables the learner profile to evolve by integrating newly generated learning evidence, thereby effectively capturing changes in learner competency, behaviour, and educational requirements throughout the learning process. Unlike static learner representations that mainly serve as descriptive inputs, the updated profile is then used as a decision-based state for KSE, which supports the estimated learner state to influence downstream personalized educational decisions. By combining heterogeneous learner information with a dynamic profile updating strategy, the presented subsystem overcomes the challenges of static learner modeling and restricted academic indicators.

C. Knowledge State Estimation Module

Following the student profile construction component, the KSE module is initiated to deliver an accurate and continuously updated representation of learner competency, which forms the basis for personalized learning decisions within the LITE-Trust framework. Previous AI-enabled learning systems mainly evaluate the learner's knowledge using static valuation scores or inadequate academic indicators, which makes them less efficient in extracting real-time learning development, detecting hidden learning gaps and accurately evaluating learner readiness for following concepts. To address these issues, the presented subsystem introduces a lightweight KSE model that employs the dynamically constructed learner profile together with multiple learner behaviour indicators, such as quiz performance, response time, learning activity patterns, revision frequency, and interaction history, to deliver a more reliable assessment of learner competency while preserving computational efficiency. The learner's knowledge state is denoted as a concept master vector, which is defined as,

$$KS_i = [ks_{i1}, ks_{i2}, \dots, ks_{in}], \;\; 0 \le ks_{ij} \le 1 \quad (3)$$

where, KS_i represents the knowledge state of the learner i, and ks_{ij} denotes the mastery level of the concept j, and n represents the number of learning concepts. This representation models learner competency at the concept level, which allows accurate detection of mastered and weak concepts instead of depending on a single assessment score. The mastery level of each concept is defined as,

$$w_{QP} + w_{RF} + w_{\mathrm{RT}} + w_{\mathrm{IH}} = 1 \quad (4)$$

Subject to

$$w_{QP} + w_{RF} + w_{\mathrm{RT}} + w_{\mathrm{IH}} \ge 0 \quad (5)$$

where QP, RF, RT, and IH represent the quiz performance, revision frequency, response time, and interaction history, respectively, while w_1, w_2, w_3, w_4 represent their respective weights. To ensure a consistent combination of heterogeneous learner indicators, the quiz performance (QP), revision frequency (RF), response time (RT), and interaction history (IH) are first normalized to a common range of $[0,1]$. Quiz performance is directly represented as a normalized score, whereas revision frequency and interaction history are scaled using min-max normalization. A lower response time generally indicates more efficient learner interaction; response time is normalized using an inverse min-max transformation. The normalized indicators are therefore defined as,

$$QP_{\{i,c\}}^{\{*\}} = QP_{\{i,c\}} \quad (6)$$

$$RF_{\{i,c\}}^{\{*\}} = \frac{RF_{\{i,c\}} - RF_{min}}{RF_{max} - RF_{min}} \quad (7)$$

$$RT_{\{i,c\}}^{\{*\}} = 1 - \frac{RF_{\{i,c\}} - RF_{min}}{RF_{max} - RF_{min}} \quad (8)$$

$$IH_{\{i,c\}}^{\{*\}} = \frac{IH_{\{i,c\}} - IH_{min}}{IH_{max} - IH_{min}} \quad (9)$$

Here, $QP^{\{*\}}, RF^{\{*\}}, RT^{\{*\}}$ *and* $IH^{\{*\}}$ denote the normalized indicators. The inverse transformation for response time ensures that a shorter response time corresponds to a higher normalized behavioural score. To provide a reproducible weighting scheme, the KSE module assigns

$$w_{\{QP\}} = 0.40, w_{\{RF\}} = 0.20, w_{\{RT\}} = 0.15, w_{\{IH\}} = 0.25 \quad (10)$$

$$w_{\{QP\}} + w_{\{RF\}} + w_{\{RT\}} + w_{\{IH\}} = 1 \quad (11)$$

The concept-level mastery score is then calculated as,

$$M_{\{i,c\}} = w_{\{QP\}} QP_{\{i,c\}}^{\{*\}} + w_{\{RF\}RF_{\{i,c\}}^{\{*\}}} + w_{\{RT\}RT_{\{i,c\}}^{\{*\}}} + w_{\{IH\}IH_{\{i,c\}}^{\{*\}}} \quad (12)$$

Here, $M_{\{i,c\}}$ represents the estimated mastery of the learner for the concept. The larger weight assigned to quiz performance reflects its direct relationship with demonstrated academic competency, while revision frequency, response behaviour, and interaction history provide complementary behavioural evidence. The resulting normalized and weighted score is subsequently used to construct the learner knowledge-state vector and readiness estimate. The weighted formulation incorporates both behavioural and academic learning evidence, which provides a more accurate evaluation of concept mastery than conventional score-based approaches. By incorporating the updated learner model that contains new evidence, the evaluated knowledge state can reflect changes in learner competency over time. The learner readiness score is calculated as,

$$LR_i = \frac{1}{n} \sum_{j=1}^{n} ks_{ij} \quad (13)$$

where, LR_i represents the learner readiness score, ks_{ij} represents the mastery level of concept j, and n represents the number of concepts. The highest value of the readiness score

demonstrates stronger prerequisite knowledge and greater readiness for following concepts. Unlike learner models that demonstrate knowledge using a single aggregate performance value, the presented KSE generates a concept-level state that can differentiate individual mastery differences over concepts and thus provide more specific information for following educational decisions. Furthermore, a knowledge graph captures conceptual relationships and concept dependencies, which enables the system to detect knowledge gaps in prerequisite concepts and evaluate learner readiness using structured knowledge reasoning. By integrating behavioural learning analytics from the learner profile with a computationally efficient architecture for knowledge graph-based reasoning. The proposed subsystem provides a continuously updated and trustworthy representation of learner knowledge. The derived concept mastery vector, learner readiness score, and identified learning gaps are then provided to ELRA as learner-state variables for educational refinement. These outputs define the personalized search space and support the optimization of academic decision variables such as AI agent selection, prompt template, learning sequence, difficulty of assessment, feedback depth, and computation resource allocation. This enables more accurate personalization and educational decision-making while preserving computational efficiency.

D. Educational Library and Readers Optimization (ELRA)

Following the KSE subsystem, the assessed learner knowledge state derived from the continuously updated learner profile is transferred to the ELRA subsystem for personalized educational decision-making. The KSE is used to estimate the students' current knowledge level and learning needs. ELRA detects the most appropriate combination of AI agents, prompts, learning sequence, valuation difficulty, feedback quality, and computational resources. Thus, KSE estimates the learners' current requirements, whereas ELRA establishes the main optimization strategy that determines how those requirements should be addressed through an appropriate educational configuration. Table III explains the purpose and novelty of the ELRA module, and Fig. 2 represents the flowchart of the ELRA subsystem.

ELRA improves the LRA, which captures information-seeking behaviour through exploration, peer-based guidance, and exploitation. However, the traditional LRA is a versatile optimizer and does not obviously integrate learner knowledge state, educational trust, and explainability. ELRA addresses these issues by introducing learner-state-guided exploration, trust-aware selection, dynamic exploitation, learner-specific configuration, and multi-objective optimization while retaining the basic LRA search principle.

1) Motivation: The selection of ELRA is guided by the precise requirements of personalized academic optimization. Traditional metaheuristic algorithms, such as GA, PSO, and other population-based methods, are primarily designed for general-purpose numerical optimization and do not naturally represent learner profiles, educational trust, or learner-oriented objectives. Alternatively, LRA provides a lightweight exploration-exploitation strategy motivated by information-searching behaviour, making it an appropriate basis for educational optimization. However, LRA does not obviously integrate learner state data or educational consistency. ELRA thus changes LRA to educational optimization by conditioning the search on the KSE-guided learner state, integrating trust into candidate evaluation and acceptance, adapting exploration to learner requirements, and collectively optimizing learning accuracy, explainability, trust, latency, and computational efficacy. This empowers ELRA to identify personalized and trustworthy educational configurations instead of generic optimization solutions.

2) Educational representation and initialization: The learner knowledge state gained from KSE is integrated into each academic configuration as,

$$I_i = [LP_i, KS, \mathbb{A}_i, \mathbb{P}_i, \mathbb{L}_i, \mathbb{D}_i, \mathbb{R}_i, \mathbb{F}_i] \quad (14)$$

where, LP_i represents the dynamic learner profile, KS represents the assessed learner knowledge state, while $\mathbb{A}_i, \mathbb{P}_i, \mathbb{L}_i, \mathbb{D}_i, \mathbb{R}_i, \mathbb{F}_i$ represents the AI agent, template of prompt, learning sequence, difficulty of assessment, computational resources, and feedback depth, respectively. These variables constitute the decision dimensions optimized by ELRA. In contrast to traditional optimizers, this representation explicitly relates the optimization variables to the learner's estimated state, which enables ELRA to search for personalized instead of standard educational configurations. This learner-state conditioning creates the search spaces as an education-specific decision space, in which optimal configurations are estimated based on the requirements of the current learner instead of general-purpose optimization solutions. The initial candidate population is defined as,

$$I_i^{(0)} = lb + r_i(ub - lb) \quad (15)$$

where, ub and lb represent upper and lower bounds and $r_i \sim u(0,1)$. This allocates candidate configurations over the search space and maintains diversity during initialization.

3) KSE-guided knowledge exploration: To adapt the exploration to educational requirements, ELRA changes the peer-guided LRA search using the learner state and trust data,

$$I_i^{P1} = I_i + \alpha_t(1 - 2r)\big(I_j - I_i\big) + \delta KS + \gamma\big(\mathcal{T}_j - \mathcal{T}_i\big) \quad (16)$$

where, I_i^{P1} represents the exploratory candidate configuration generated for the candidate i, I_i represents the current candidate configuration, I_j is a peer candidate reader, $r \sim u(0,1)$, $\mathcal{T}_j, \mathcal{T}_i$ represents the trust scores of the current and peer configurations, α_t regulates the exploration magnitude, δ regulates the learner knowledge state influence, and γ denotes the trust-based exploration coefficient, which controls trust-based movement.

The conventional LRA update, which primarily uses peer-candidate information to determine the search direction, is augmented by the proposed ELRA update introduces two additional sources of optimization guidance: the learner knowledge state and the trust difference between candidate configurations. The learner-state term biases exploration toward configurations that address the learner's identified knowledge gaps and learning requirements, whereas the trust

term discourages movement toward configurations with lower educational reliability. The search direction is no longer determined solely by the geometric relationship between candidate solutions. Instead, ELRA produces a learner- and trust-conditioned search trajectory. This modification is algorithmic because it changes the candidate-generation rule itself and directly affects which configurations are explored during optimization.

Unlike the traditional LRA update, the presented formulation directs exploration based on both learners' needs and trust differences, instead of relying solely on peer information. This change prevents the exploration process from treating all candidate configurations equally and enables the search direction to remain stable with both the learners' estimated needs and the trustworthiness of the educational configuration.

4) Trust-aware evaluation: Every explored configuration is estimated using the trust value of the candidate configuration, which is defined as,

$$\mathcal{T}_i = w_1 FC_i + w_2 + w_3 C_i + w_4(1 - HP_i) + w_5 EQ_i + w_6 EC_i \quad (17)$$

where, $FC_i, CA_i, C_i, HP_i, EQ_i, and\ EC_i$ represents factual correctness, curriculum alignment, confidence, hallucination probability, explanation quality, and educational completeness, respectively, with $\sum_{i=1}^{6} w_i = 1$. A candidate undergoes refinement only when $\mathcal{T}_i \geq \mathcal{T}_{min}$. This trust limitation introduces a quality gate into the optimization process, which prevents candidates with unreliable or low-quality educational reliability from proceeding to refinement, instead of enabling fitness enhancement alone to determine candidate progression.

5) Trust and state-guided adaptive exploitation: For trusted configurations, ELRA performs adaptive optimization as

$$I_i^{P2} = I_i + \varepsilon_t(1 - 2r)\frac{\|ub - lb\|}{dt} + \omega\left(\mathcal{T}_j - \mathcal{T}_i\right) + \gamma(KS - EC_i) \quad (18)$$

where, I_i^{P2} represents the optimized candidate configuration, I_i represents the current candidate, ε_t regulates the exploitation step, d represents the decision variables count, t denotes the iteration number, r denotes a random variable; it is retained in the equation, ub, lb denotes the upper and lower bounds, γ denotes the learner-state influence coefficient, and EC_i represents the knowledge state needed to be associated with the current configuration. The gradually decreasing step size allows broader exploration in early iterations and fine-tuning in later iterations. The trust and state terms limit the optimization direction based on configuration reliability and learner-specific needs. This, while retaining the regular exploitation principle, is retained from LRA; ELRA conditions the optimization process on the evaluated knowledge state and configuration trustworthiness instead of depending only on numerical fitness improvement.

6) Trust-aware acceptance and convergence: A candidate substitutes the current configuration only when it meets trust, fitness, and learner-specific conditions,

$$I_i(t+1) = \begin{cases} I_i^{P2}, & \mathcal{T}_i^{P2} \geq \mathcal{T}_{min} \wedge F_i^{P2} < F_i \wedge \mathcal{A}(KS, I_i^{P2}) > \mathcal{A}(KS, I_i) \\ I_i, & otherwise \end{cases} \quad (19)$$

where, $I_i(t+1)$ represents the updated candidate configuration, I_i^{P2} denotes the optimized candidate $\mathcal{T}_i^{P2}$ represents the optimized candidate trust score, $\mathcal{T}_{min}$ denotes the minimum acceptable trust threshold, F_i^{P2} represents the optimized candidate fitness. ELRA minimizes the fitness function $F_i^{P2} < F_i$ indicates an objective improvement. $\mathcal{A}(KS, I_i)$ calculates the alignment between the learner's knowledge state and academic configuration. ∧ represents logical AND, requiring all three conditions simultaneously. Therefore, ELRA accepts a promising solution only if it meets the trust requirements and improves the overall objective, and achieves better alignment with the learner state. This acceptance strategy prevents a candidate from being selected solely because of numerical objective enhancement, thus maintaining learner-specific suitability during the final solution-selection stage. The process ends when the highest iteration count is reached, or the enhancement becomes negligible. To ensure mathematical consistency and reproducibility, all learner-state, trust, alignment, and continuous configuration variables used by ELRA are represented in compatible normalized spaces. Let the learner knowledge state be represented by the concept mastery vector.

$$K_i = \left[k_{\{i1\}}, k_{\{i2\}}, \dots, k_{\{iC\}}\right]^{\{T\}} \in [0,1]^C \quad (20)$$

Here, C denotes the number of learning concepts and $kick_{\{ic\}}$ represents the estimated mastery of learner i for concept c. The corresponding learner-state vector used by ELRA is a C-dimensional normalized vector. An educational configuration is represented by

$$X_i = [a_i, p_i, l_i, d_i, r_i, f_i]^{\{T\}} \quad (21)$$

Here, a_i denotes the selected AI-agent configuration, p_i denotes the prompt-template configuration, l_i denotes the learning-sequence configuration, d_i denotes assessment difficulty, r_i denotes computational-resource allocation, and f_i denotes feedback depth. For numerical compatibility, continuous decision variables are normalized to [0,1] as

$$x_{\{ij\}}^{\{*\}} = \frac{x_{ij} - x_j^{min}}{x_j^{max} - x_j^{min}} \quad (22)$$

Here, x_j^{max}, x_j^{min} denote the lower and upper bounds of the j-th decision variable. Categorical variables, such as agent and prompt selections, are represented by their predefined valid indices or one-hot configurations and are mapped back to their corresponding discrete values after optimization. The exploration and exploitation operations are performed in a common normalized decision space. The learner-state influence is incorporated through a dimension-compatible mapping

$$g(K_i, X_i) = W_{KK_i} - W_{XX_i} \quad (23)$$

Here, W_{KK_i}, W_{XX_i} are dimension-matching projection matrices that map the learner-state and configuration

representations into the same d-dimensional optimization space. The trust score is normalized to the interval [0,1] and is calculated as:

$$T(X_i) = w_F F_i + w_C C_i + w_Q Q_i + w_E E_i + w_H(1 - H_i) + w_G G_i,\ \sum_m w_m \geq 0 \quad (24)$$

Here, $F_i, C_i, Q_i, E_i, H_i\ and\ G_i$ represent factual correctness, curriculum alignment, confidence, explanation quality, hallucination probability, and educational completeness, respectively. The transformation $(1 - H_i)$ converts hallucination probability into a positive reliability measure. The learner-configuration alignment is similarly normalized as

$$A(K_i, X_i) = 1 - \frac{\|g(K_i, X_i)\|_2}{\sqrt{d}} \quad (25)$$

A larger value of A indicates stronger compatibility between the learner's estimated knowledge requirements and the candidate educational configuration. Using these normalized quantities, the ELRA fitness function is expressed as

$$J(X_i) = w_L L(X_i) + w_T T(X_i) + w_A A(K_i, X_i) - w_R R(X_i) - w_C C(X_i) \quad (26)$$

Here, L denotes learning-performance utility, T denotes trust, A denotes learner-configuration alignment, R denotes response latency, and C denotes computational cost. All terms are normalized to [0,1], and the weights satisfy

$$w_L + w_T + w_A + w_R + w_C = 1 \quad (27)$$

The ELRA optimization with best configuration is consequently defined as

$$X^* = \underset{X \in \Omega}{\operatorname{argmax}} J(X) \quad (28)$$

This formulation establishes a common normalized representation for learner state, educational configuration, trust, and alignment and explicitly defines the feasible search space, objective function, acceptance conditions, and convergence criterion.

7) Multi-objective fitness function: ELRA collectively optimizes learning accuracy, trust, explainability, latency, and computational cost.

$$F(I) = \aleph_1(1 - L_A) + \aleph_2(1 - \mathcal{T}) + \aleph_3(1 - E) + \aleph_4 L + \aleph_5 C_C \quad (29)$$

where, $L_A, \mathcal{T}, E, L, and\ C_C$ represents normalized learning accuracy, normalized trust, normalized explainability, normalized latency, and normalized computational cost, respectively, and $\aleph_1, .., \aleph_5$ denotes the objective weights, $\sum \aleph_i = 1$. In order to compare different objectives with each other, all five objectives were normalized to a scale of [0,1]. The benefit objectives, including learning performance, trust, and explainability, were normalized using min-max normalization as $X_i' = (X_i - X_i^{min})/(X_i^{max} - X_i^{min})$. The cost objectives, including latency and computation cost, were inversely normalized as $X_i' = (X_i^{max} - X_i)/(X_i^{max} - X_i^{min})$.

In addition to modifying candidate exploration, ELRA changes the candidate evaluation and acceptance process. For a candidate configuration XX, the optimization objective considers learning performance, trustworthiness, explainability, latency, and computational efficiency. This constrained acceptance mechanism distinguishes ELRA from conventional LRA, in which candidate evolution is primarily governed by the search and fitness mechanism. In ELRA, an improvement in the numerical objective alone is insufficient when the candidate does not satisfy the required trust and learner-alignment conditions. Thus, higher normalized values indicate better performance for all objectives, while the original cost measures are minimized. Afterwards, the normalized objectives were aggregated using the weighted objective configurations in Table XX, where the weighting groups represent different priorities among learning performance, trust, and efficiency. This design supports the sensitivity analysis to examine how changes in objective priorities affect the overall fitness and learning performance. The optimal configuration is obtained as,

$$I' = \arg\min_I F(I) \quad (30)$$

Subject to

$$\mathcal{T}(I) \geq \mathcal{T}_{min} \quad (31)$$

where, $\mathcal{T}_{min} = 0.70$. This mathematical representation balances personalized learning efficiency, educational consistency, interpretability, response effectiveness, and resource consumption, thus treating educational optimization as a multi-criteria decision problem instead of relying solely on learning performance. In contrast to the conventional LRA objective, which is not formulated around these academic criteria, ELRA assesses promising configurations based on a unified educational objective that collectively includes effectiveness, interpretability, trustworthiness, computational efficiency and responsiveness.

The computational complexity is approximately $O[tn(F_C + T_C)]$, where t denotes the iteration count, n represents population size, F_C represents fitness cost, and T_C represents trust cost. The additional trust and learner-state evaluations introduce minimal computational cost while maintaining the lightweight population-based structure of LRA. Hence, ELRA is not only a relabeling of LRA; its exploration, optimization, and acceptance strategy explicitly integrate learner-state and trust information to generate personalized education configurations. The conventional LRA performs exploration and exploitation primarily through peer-guided candidate movement within a general optimization space. Its search behavior is determined by the current candidate, a peer candidate, and the corresponding search coefficients. In contrast, ELRA retains the basic exploration–exploitation principle of LRA but introduces learner-state conditioning, trust-aware candidate evaluation, and learner-specific acceptance constraints. Therefore, ELRA modifies the search dynamics rather than merely applying LRA to an educational task. ELRA extends this formulation by conditioning the candidate movement on the learner knowledge state and the trust difference between configurations. The search direction in ELRA is jointly determined by peer information, learner requirements, and trustworthiness. ELRA introduces a trust-

gated refinement mechanism. A candidate configuration is permitted to enter the subsequent optimization stage only when

$$T(X_{it}) \geq \tau_T, T(X_i^t) \geq \tau_T \quad (32)$$

Here, τ_T is the predefined trust threshold. The accepted candidate is then evaluated according to both optimization quality and learner-configuration alignment. This introduces a constraint that is absent from the conventional LRA search process. The principal algorithmic distinction of ELRA is the transformation of an unconstrained peer-guided search into a learner-conditioned, trust-gated, and multi-objective educational optimization process.

TABLE III. PURPOSE AND NOVELTY OF ELRA MODULE

ELRA Module	Conventional LRA	Proposed ELRA Extension	Technical implication
Educational reader	General candidate/search representation	It represents AI agent, prompt, learning, feedback, assessment, and resources	Generates a learner-specific academic-search space
Knowledge exploration	Peer-guided exploration based on information-seeking patterns	Exploration is driven by the KSE-guided learner knowledge state and trust in information	Guides the search toward configurations aligned with the learners' current requirements
Trust evaluation	Candidate quality is mainly established through optimization fitness	Evaluates factual correctness, hallucination, curriculum alignment, explanation quality, and educational completeness	Presents educational trustworthiness in candidate evaluation
Candidate selection	Candidate evolution follows the traditional search and fitness strategies	Candidates should satisfy a minimum trust threshold before further optimization	Prevents untrustworthy educational configurations from entering additional optimization
Adaptive exploitation	Traditional exploitation of promising search regions	Exploitation is dynamically guided by learner state, trust, and iteration-dependent step size	Guides fine-tuning toward learner-aligned and reliable configuration while gradually reducing the search step
Candidate acceptance	Selection is mainly based on enhancement within the optimization process	Acceptance includes trust, objective enhancement, and learner-configuration alignment	Maintains both solution quality and learner-specific fitness
Objective formulation	General optimization objective	Collectively optimizes learning accuracy, explainability, trust, latency, and computational cost	Adapts the search into an academic-specific multi-objective optimization problem
Final solution	Generally optimized candidate	Trustworthy configuration aligned with the learner's knowledge state and academic requirements	Generates a learner-specific, resource-aware, and trustworthy academic configuration for personalized decision-making

Pseudocode of ELRA module

Input: learner profile $L_P, , lb, ub,$ knowledge state KS, population size n, maximum iteration $\mathcal{T}_{max}$, trust threshold $\mathcal{T}_{min}$, and convergence tolerance ε
Output: optimal educational configuration I'
Initialize population $I_i^{(0)}$ using Eq. (8) $i = 1, \dots, n$
Evaluate fitness $F(I_i)$ using Eq. (13) and trust score $\mathcal{T}_i$ using Eq. (10) for each I_i
Select the optimal trusted configuration I'
For t=1 to $\mathcal{T}_{max}$ do
For i=1 to n do
Select optimal configuration I_j, where $j \neq i$
Generate experimental configuration I_i^{P1} using Eq. (9)
Compute trust score $\mathcal{T}_i^{P1}$ using Eq. (10)
If $\mathcal{T}(I) \geq \mathcal{T}_{min}$ then
Generate optimized configuration I_i^{P2} using Eq. (11)
Compute fitness $F(I)$ using Eq. (13), trust score $and\ \mathcal{T}_i$ using Eq. (10), and learner-configuration alignment
If $\mathcal{T}(I) \geq \mathcal{T}_{min}$ the learner-state requirements satisfy Eq. (11), then
Update as the trusted candidate with minimum fitness
End if
End if
End for
Update the population toward the trusted candidate using Eq. (9)
If the convergence condition is satisfied, then break
End for
Return I'

E. Lightweight Multi-Agent Coordinator

Following the KSE and ELRA subsystems, the optimized academic configuration produced by ELRA, such as selected AI agent prompt templates, learning sequence, assessment difficulty, feedback depth, and computational resource allocation, is directly fed into the activation strategy of the lightweight multi-agent coordinator. The multi-agent coordinator is responsible for deciding which agents are responsible for delivering it, which includes the tutor, assessment, feedback, recommendation, and academic integrity agents. However, all agents being active for each interaction would involve high computational costs and delays; the presented module introduces context-adaptive agent activation. The tutor agent offers explanations and guidance, the assessment agent computes learner performance, the feedback agent provides feedback to the learner, the recommendation agent selects relevant learning resources, and the academic integrity agent validates content and activities for academic integrity issues. Their specialized roles enable educational tasks to be dynamically allocated based on the learners' current requirements. Every educational agent is implemented as a task-specific role, based on a shared Generative Pre-trained Transformer 4 omni (GPT-4o) mini language model, rather than a separate model. Every agent takes the learner knowledge state, ELRA-optimized configuration, and task-specific context as inputs, and outputs role-specific responses, such as explanations, evaluations, feedback, learning-resource recommendations, or integrity checks, respectively. The coordinator calculates the relevance of every agent from the

current learning context and learner-state/ELRA configuration, activates the agents whose relevance scores exceed the activation threshold, and respects the quality and computational-cost constraints (Eq. (16)-(18)). The relevance score is determined according to the compatibility between the current academic task, the KSE-derived learner knowledge state, and the ELRA-optimized academic configuration. Thus, agent activation is learner- and task-dependent instead of based on a derived execution sequence. The active agent set is defined as,

$$AG_t = \{a_j | r_j(KS, I', C_{Et}) \geq \theta_j\} \quad (33)$$

where, AG_t represents the set of active agents at iteration t, a_j represents the j-th educational agent, $r_j(.)$ represents the relevance score of agent j, C_{Et} represents the current learning context, I' denotes the ELRA-optimized educational configuration, and θ_j denotes the activation threshold. Thus, agents are activated only when their relevance scores exceed the specified threshold. This KSE-and ELRA-based selection minimizes unnecessary agent execution and identifies the gap in redundant multi-agent processing and maximizes response latency. The selected agent outputs are denoted as,

$$OP_t = Cf(\{OP_j : j \in AG_t\}, KS, I') \quad (34)$$

where, OP_t represents an active agent j output and $Cf(.)$ represents the agent coordination function. By integrating KS and I', the coordinator produces agent outputs based on the learners' state and personalized educational requirements, thus identifying isolated agent operation and unreliable responses. To reduce agent utilization while preserving educational quality, the optimal active set is defined as,

$$AG_t' = \arg\min_{AG_t} [\lambda_c | AG_t + \lambda_l L_t] \; s.t \; RQ(AG_t, KS, I') \geq RQ_{min} \quad (35)$$

where, $|AG_t|$ represents the active agent count, $\lambda_c, and\ \lambda_l$ represents the weight values of computational cost and response latency. The coefficients satisfy $\lambda_c, \lambda_l \geq 0, \lambda_c + \lambda_l = 1$. L_t denotes response latency, and RQ denotes educational response quality, and RQ_{min} denotes the minimum acceptable response quality.

This mathematical representation identifies the minimum set of agents that meets the required quality, which provides the major contribution of lightweight, quality-based multi-agent implementation. Thus, agent selection is formulated as a forced active -set decision that collectively considers educational quality and processing cost, instead of evaluating the relevance of each agent individually. Overall, the subsystem contributes learner-based, ELRA-driven, dynamically activated, and quality-based multi-agent coordination, which addresses redundant computation, latency, isolated agent operation, and unreliable educational responses. Table IV emphasizes the practical contribution of every specialized agent and its role in the designed framework. In contrast to traditional multi-agent systems that mainly combine individual agents, the presented coordinator assigns learner-personalized responsibilities and adaptively activates agents based on the KSE-based state and ELRA-optimized configurations.

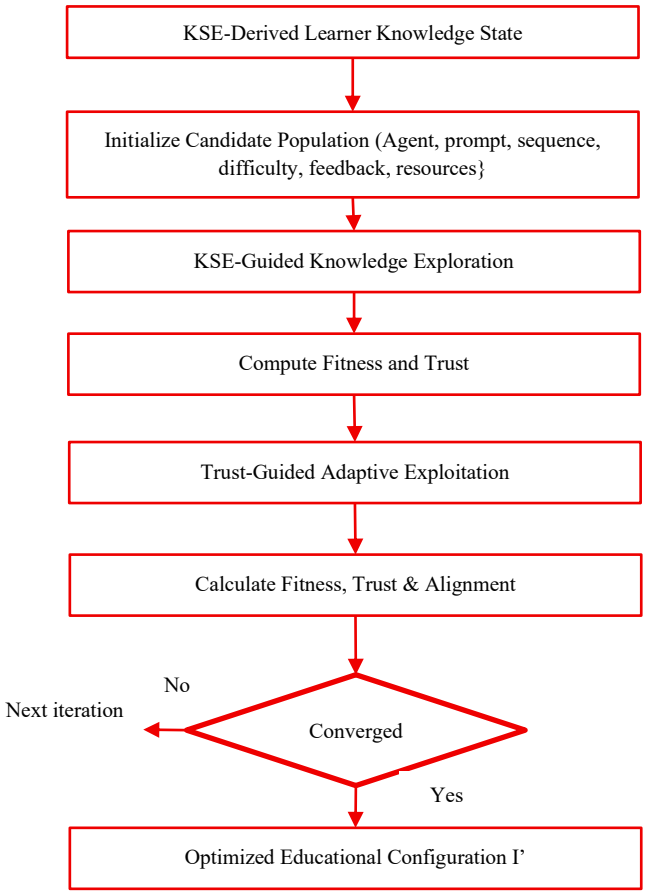

Fig. 2. Flowchart of ELRA module.

TABLE IV. CONTRIBUTION OF MULTI AGENTS

Agents	Proposed Contribution
Tutor Agent	Provides explanations and guided learning based on the KSE-based learner state, which enables personalized knowledge support.
Assessment Agent	Produces and evaluates assessments using the ELRA-adapted difficulty, which allows learner -adaptive assessment.
Feedback Agent	Delivers targeted corrective and formative feedback with an appropriate level of depth, which supports knowledge-gap-specific learning support.
Recommendation Agents	Chooses learning resources and activities based on KS, and I', which enables optimization-based resource personalization.
Academic Integrity Agent	Evaluates academic content and activities before delivery, which provides trust-aware integrity verification throughout the learning pipeline.

F. Explainability Engine

Following the Lightweight Multi-agent coordinator, the outputs of the selected agents OP_t along with the KSE-based learner state KS_i and ELRA-optimized configuration I' are offered to the explainability engine. While personalized AI decisions can enhance learning outputs, their limited transparency may reduce trust among learners and instructors. Thus, the presented engine produces explanations, reasoning, and confidence for each academic decision, which identifies the interpretability gap in AI-based personalized education. The explanation is expressed as,

$$EX_t = \varepsilon(KS_i, I', OP_t, E_{ct}) \tag{36}$$

where, EX_t represents the produced explanation, $\varepsilon(.)$ represents the explainability function, I' represents the ELRA-optimized configurations, and E_{ct} represents the learner's current educational context. The formulation is conditioned on the learner state, optimized configurations, and agent outputs, explaining why a concept was learned, why assessment difficulty was chosen, why a revision action was taken, or why a learning resource was recommended, thus addressing the issue of context-free recommendations. The decision reasoning and confidence are obtained as,

$$DR_t = DR(KS_i, I', OP_t), S_t = S(DR_t) \tag{37}$$

where, DR_t represents decision reasoning and S_t represents the respective confidence score. $DR\,(.)$ represents the reasoning generation function, $S(.)$ represents the confidence estimation function; both quantities are derived from the learner state, optimized configuration, and coordinated agent output. Hence, the engine explains the rationale for each decision and its confidence level, thereby enhancing educational transparency and instructor confidence. The final explainable output is formulated as,

$$Z_t = \{EX_t, DR_t, S_t\} \tag{38}$$

where, Z_t collectively represents explanation, reasoning, and confidence. This formulation connects the generated explanation to the information that contributed to the educational decision, which facilitates the rationale to reflect the learner-specific state and optimal educational configuration instead of generating individual generic explanations. Hence, the presented engine provides learner-state-aware and ELRA-based explanations, reasoning, and confidence, thereby bridging the transparency and trust gap in personalized academic decision-making.

G. Trust Evaluation Engine

Following the explainability engine, the trust evaluation engine executes final trust validation of the educational response produced by the optimal agents. While ELRA already computes trust during optimization, that estimation is used to select optimal candidate configurations. Unlike the presented trust evaluation engine, which validates the actual produced response prior to delivery, it addresses the gap between trustworthy configuration selection and trustworthy final academic output. The final response trust score is expressed as,

$$T_{St} = w_{fc}FC_t + w_{ca}CA_t + w_h(1 - H_t) + w_cC_t \tag{39}$$

Subject to:

$$w_{fc} + w_{ca} + w_h + w_C = 1 \tag{40}$$

where, T_{St} represents the final response trust score of the generated response, FC_t represents factual correctness, CA_t represents curriculum alignment, H_t represents hallucination probability, and C_t denotes confidence. While w_{fc}, w_{ca}, w_h, w_C represents their respective weights. The term $1 - H_t$ transforms the estimated hallucination probability into a respective reliability measure. Hence, the mathematical representation collectively evaluates factual reliability, curriculum suitability, hallucination risk, and confidence, instead of depending solely on model-generated confidence. A response is accepted only when

$$T_{St} \geq T_{S_{min}} \tag{41}$$

where, T_{St} represents the final response trust score, and $T_{S_{min}}$ represents the minimum acceptable response threshold. All trust components are normalized to [0,1], making $T_{St} \in [0,1]$. A response satisfying $T_{St} \geq T_{S_{min}}$ is accepted for delivery, whereas a response below this threshold is rejected or refined before delivery. In the experimental configuration, the trust threshold is fixed at 0.70. For this final step, the produced response is evaluated against both the corresponding educational knowledge and reference information for the associated learning task. Factual correctness is established by comparing the derived responses to the provided reference information. Meanwhile, the degree of alignment with the curriculum is determined by the target concept and its requirements. Thus, hallucination probability is defined as the ratio of inaccurate information that was found in comparison with the reference information during fact-checking. The confidence score is extracted from the model confidence assessment. Finally, these metrics are used to inform the response-level acceptance decision. The threshold therefore functions as a response-level acceptance limit, which makes trust evaluation an active control strategy instead of only a post -hoc reliability indicator. Hence, the presented engine acts as a final trust-aware integrity control, which prevents undependable educational responses from reaching the learner. Unlike ELRA, in which trust drives the candidate configuration selection and optimization, this component analyses the final agent's response. This two-stage trust strategy boosts the developed framework by incorporating both learning processes: the trust-aware educational optimization and final fact-checking step, which improves the accuracy of hallucination-free and curriculum-aligned educational content while enabling more reliable personalized decision-making.

H. Academic Integrity Analyzer

Following the trust evaluation engine, the academic integrity analyzer estimates whether AI-assisted learning maintains originality, critical thinking, independent problem-solving, and authentic learning behaviour. Traditional integrity methods focus primarily on plagiarism, which may overlook excessive AI dependency and reduced learner independence. Hence, the introduced analyzer aims to mitigate these issues by monitoring the authenticity and adequacy of AI-assisted learning. The educational integrity score (I_{At}) is expressed as,

$$I_{At} = w_1 OR_t + w_2 CT_t + w_3 PS_t + w_4 AL_t \quad (42)$$

Subject to

$$w_1 + w_2 + w_3 + w_4 = 1 \quad (43)$$

where, OR_t represents originality, CT_t represents thinking, PS_t represents independent problem-solving, and AL_t represents authentic learning behaviour, each estimated from relevant learner interaction and performance patterns available in EdNet and OULAD. $w_1, \dots, w_4$ represents corresponding weight values $w_k \geq 0 \sum w_k = 1$. The weighted formulation integrates multiple behavioural indicators, thereby delivering a more holistic integrity assessment than plagiarism detection alone. AI dependency is evaluated as,

$$AD_t = \frac{\zeta_{AI}}{\zeta_{AI} + \zeta_I} \quad (44)$$

where, AD_t represents the estimated AI-dependency score, ζ_{AI} represents AI-assisted interactions, and ζ_I represents independent learning interactions. A maximum AD_t represents greater AI dependency. Higher AD_t indicates greater reliance on AI-assisted interactions. The integrity need is satisfied when $AI_t \geq AI_{min}$, $AD_t \leq AD_{max}$ where AI_{min} represents the minimum integrity score and AD_{max} represents the maximum acceptable AI dependency. These constraints ensure that AI assistance does not take over from genuine human learning. The indicators identified by the academic integrity analyzer should be regarded as behavioural estimates rather than measures of academic integrity. In fact, EdNet and OULAD provide information on the learning process and its outcomes, from which integrity and the extent to which students rely on AI are inferred. Put another way, since the input data cannot provide ground truth about academic integrity and AI reliance, the analyzer does not claim to directly assess these aspects, but rather it identifies learning behaviours that may indicate academic integrity issues and/or reliance on AI. Therefore, the contribution of the proposed work is an AI-aware, behaviour-based integrity check that builds upon the preceding trust verification and aims to bridge the plagiarism-centric gap in academic integrity assessment.

The academic-integrity component is currently evaluated using behavioral indicators derived from learner interaction patterns rather than independently annotated ground-truth integrity labels. Therefore, its outputs should be interpreted as risk indicators for potential academic-integrity concerns, rather than definitive evidence of misconduct. The framework does not claim to establish academic-integrity violations solely from these behavioral estimates. Validation against expert annotations or independently labeled behavioral indicators is identified as an important direction for future evaluation.

I. Personalized Learning Dashboard

Following the academic integrity analyzer, the personalized learning dashboard introduces the learners' learning analytics, personalized learning recommendations, concept-level progress, knowledge gap alerts, trust alerts, and academic-integrity alerts using a lightweight interface. Traditional educational dashboards provide learning information to a learner in a non-adaptive manner. Instead, the presented dashboard employs KSE-derived learner state, ELRA-optimal configuration, multi-agent outputs, trust assessment, and academic integrity results to provide an integrated learner view. The dashboard limits the information that is relevant to the learning context, such as the level of mastery, recommendations of resources, learning needs, assessment results, trust alerts, and academic-integrity alerts, thus enabling faster processing of the information and interaction.

The novelty of LITE-Trust lies in the explicit dependencies among the proposed methods rather than the individuality of each technique used. In particular, while the continuously updated learner profile informs KSE, KSE informs the learner's knowledge state for ELRA, the latter informing the educational configuration that determines the agent's selection. The response is then evaluated by the trust engine. As such, it can be argued that the mathematical formulations describe a learner-state-driven decision-making process where each step informs the next one rather than several independent procedures combined together.

The LITE-Trust framework is designed to perform lightweight execution through compact KSE, limited iterations of ELRA, selective agent activation, and optimized prompt and retrieval processes. First, KSE reduces subsequent operations by using a compact knowledge-state representation. ELRA further limits search by considering a fixed population size and iterations. Finally, dynamic coordination allows for activating only specific agents according to the incoming request. In addition, prompt optimization and dense-vector-retrieval reduce additional computational burdens. Hence, the efficiency gains mainly result from reduced representation, limited optimization step, selective execution, and retrieval-generation costs. The reported parameter count excludes the parameters of the external LLM employed by LITE-Trust.

J. Computational Complexity Analysis

The computational efficacy of LITE-Trust is achieved through the implementation of lightweight KSE representation, reduced ELRA search, optimal agent activation, and optimized prompt and retrieval processing. The overall computational complexity is then decomposed based on the major processing components of LITE-Trust. The KSE component requires $O(nl)$, where n represents the count of learner records, andan l represents the average learner-interaction sequence length. This follows because each of the n learner records processes an average of l interaction elements. ELRA requires $O(tnF_C)$, where t denotes the iteration count, n represents population size, F_C represents fitness estimation cost for one candidate solution. Therefore, n candidates are evaluated during each of t iterations. Dynamic agent selection ,requires $O(V + k)$ in the worst case and $O(k)$ after selective activation, where V is the total number of available agents and k is the number of activated agents. Since LITE-Trust achieves only the agents required for a particular learis ner request, $k \ll V$ in a typical execution, thereby avoiding unnecessary agent computation and reducing inference latency and utilization. Trust evaluation requires $O(kq)$, where q represents the cost of computing the trust-related indicators. Explainability processing requires $O(e)$, representing the cost of generating and processing the corresponding explanations, where e denotes the number of explanatory factors. Finally, retrieval and generation require

$(\log N + r + C_g)$, where N represents the indexed knowledge-base size, r represents the number of retrieval items, and C_g represents generation cost. Consequently, the overall computational complexity is derived as the sum of the component complexities $C_{LITE-Trust} = O(nl + tnF_C + V + k + kq + e + \log N + r + C_g)$. This component-wise formulation reflects the actual operations performed by each module. The presented lightweight design reduces computational complexity through compact KSE representation, bounded ELRA search, selective agent activation, and optimized retrieval and generation, thereby reducing unnecessary computation and inference latency while preserving the required educational quality.

To provide a more realistic efficiency assessment, the computational analysis considers the complete execution pipeline rather than only the local algorithmic complexity. The evaluation accounts for GPT-4o mini API invocation, embedding generation, retrieval operations, multiple-agent execution, trust verification, and ELRA optimization iterations. For each request, end-to-end latency is considered together with local processing time, API response time, network communication overhead, and the number of activated agents. External inference and API usage costs are also recognized separately from the computational cost of the locally deployed components. This end-to-end assessment provides a more representative measure of the practical efficiency of LITE-Trust.

IV. Results and Discussion

A. Experimental Environment and Datasets

The LITE-Trust framework is experimentally evaluated using two benchmark educational learning analytics datasets, such as OULAD and EdNet. These datasets provide the necessary learner interaction, assessment, and activity data required to evaluate the proposed learner knowledge estimation, personalized optimization, adaptive agent coordination, trust evaluation, and academic-integrity analysis modules. OULAD contains learner demographic information, valuation results, module information, and Virtual Learning Environment (VLE) interactions, which enable learner progress analysis and behavioural pattern analysis. EdNet provides large-scale learner-question interaction data, which includes question attempts and response histories, that supports concept-level knowledge estimation and personalized learning analysis.

The EdNet and OULAD primarily provide learner interaction, assessment, and educational-process information. These datasets are therefore used to construct learner profiles, estimate knowledge states, and evaluate personalized learning performance. For generated educational content, hallucination, trust, explainability, and academic-integrity evaluation, the dataset records are supplemented with corresponding reference answers, learning objectives, and required educational information where applicable. These references provide the basis for checking factual consistency, content relevance, explanation quality, and unsupported information. The evaluation criteria are applied consistently across all responses, while dataset-derived learner information is kept separate from the ground-truth information used for content-level validation.

TABLE V. Description of the OULAD and EdNet Datasets used for Training and Testing the LITE-Trust

Dataset	Category	Total	Training (80%)	Testing (20%)
OULAD	Students	32,593	26,074	6,519
	VLE interactions	10,655,280	8,524,224	2,131,056
EdNet	Students	784,309	627,447	156,861
	Interactions	131,441,538	105,153,230	26,288,307

Table V represents the dataset descriptions, which include total samples and training and testing samples. For both datasets, the data were split into 80% training and 20% test samples at the level of learners so that no interactions from the same learner would appear in both train and test sets. For the purposes of the experiments described in this study, the evaluation was carried out in five independent runs with random seeds 11, 22, 33, 44, 55, while preserving the same learner-level split protocol across all runs. The values reported for the experiments are the mean ± standard deviation over the five runs. The test set was kept hidden during training, parameter tuning, and optimization.

TABLE VI. Hardware and Software Configuration used for Experimental Evaluation

Hardware Configuration	
Processor	Intel Core i7-12700H, 14 cores
Storage	512 GB SSD
RAM	16GB
Software Configuration	
Operating system	Ubuntu 22.04 LTS
Programming Language	Python 3.9
Development environment	Pycharm
Embedding API	Text-embedding-3-small

TABLE VII. Parameter Configuration and Experimental Settings of the LITE-Trust

Parameters	Value
LLM	GPT-40-mini (external API)
Embedding model	Text-embedding-3-small (external API)
Agent activation	Context-adaptive
Tokenization	Standard tokenizer
Retrieval	Dense-vector similarity search
Trainable parameters	1.92 M (LITE-Trust components only)
Prompt strategy	Compact context-aware prompt
KSE weight constraint	$\sum_j w_j = 1$
ELRA population size	30
ELRA exploration coefficient	0.5
ELRA exploitation coefficient	0.5
ELRA maximum iterations	100
Trust threshold	0.70
Agent activation threshold	0.70
Convergence tolerance	0.001

Table VI represents the system configuration, and Table VII illustrates the parameter configuration of the LITE-Trust framework. The reported 1.92 M trainable parameters are for the locally deployed LITE-Trust components only; the externally accessed models (GPT-4o mini and text-embedding-3-small) are not included. The costs associated with the external LLM and embedding services, such as network/API latency and generated cost, are treated separately from the computational costs of the locally deployed LITE-Trust components. Here, the activation threshold was fixed at 0.70 across all experiments to maintain a stable relevance criterion for selective agent execution.

B. Evaluation Metrics

1) Educational performance

a) Knowledge gain: It is generally denoted by the improvement in the learner's knowledge from the pre-learning assessment to the post-learning assessment, which is expressed as,

$$G_K = \mathfrak{H}_{post} - \mathfrak{H}_{pre} \tag{45}$$

where, $\mathfrak{H}_{post}$ represents the pre-learning assessment score, and $\mathfrak{H}_{pre}$ represents the post-learning assessment score.

b) Prediction accuracy: It is given by the ratio of the number of true responses identified by the learners, which is defined as,

$$ACC = \frac{T_P+T_N}{T_P+T_N+F_P+F_N} \tag{46}$$

where, T_P, T_N, F_P, F_N represents true positive, true negative, false positive, and false negative, respectively.

c) F1-Score: It is used to measure the balance between precision and recall, which is expressed as,

$$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{47}$$

d) Recommendation precision and recall: Precision is used to measure the percentage of relevant recommendations among the selected resources, while recall is used to measure the percentage of relevant resources that were effectively recommended.

$$RP = \frac{T_{PR}}{T_{PR}+F_{PR}}, RR = \frac{T_{PR}}{T_{PR}+F_{NR}} \tag{48}$$

where, $T_{PR}, F_{PR}, and\ F_{NR}$ represent recommended relevant resources, recommended irrelevant resources, and relevant but unrecommended resources, respectively.

e) Student satisfaction: It is used to measure the average learner satisfaction according to the adopted questionnaire or Likert-scale responses, which is defined as $S_S = \frac{1}{m}\sum_{i=1}^{m} \mathcal{s}_i$. Where $\mathcal{s}_i$ represents the learner satisfaction score, and m represents the participating learners' count.

2) Trustworthiness

a) Trust score: It is used to measure the overall trustworthiness of the produced educational outcomes by incorporating factual correctness, confidence, curriculum alignment, explanation quality, and educational completeness. The trust score is expressed as, $T_S = \sum_{l=1}^{m} w_l T_l,\ \sum_{l=1}^{m} w_l = 1$ Where T_l represents each trust-relevant measure and w_l represents its respective weight value.

b) Hallucination Rate: It is used to measure the percentage of produced responses containing unsupported or inaccurate information, which is expressed as,

$$H_R = \frac{n_h}{n_g} \times 100 \tag{49}$$

where, n_h represents the count of responses including hallucinated information and n_g represents the total count of generated responses. A reduced hallucination rate indicates the highest trustworthiness. To calculate the relative enhancement in hallucination control, the hallucination reduction is formulated as,

$$HR_{rd} = \frac{H_{R,base}-H_{R,LITE}}{H_{R,base}} \times 100 \tag{50}$$

where, HR_{rd} denotes the hallucination reduction, $H_{R,base}$ denotes the hallucination rate of the LLM-based tutoring baseline, and $H_{R,LITE}$ denotes the hallucination rate of LITE-Trust under the same evaluation protocol. Hence, the hallucination reduction demonstrates the relative decrease in hallucinated responses obtained by Trust compared with the selected baseline.

c) Factual consistency: Factual consistency refers to the percentage of responses that are factually consistent with educational knowledge or reference information, which is expressed as,

$$F_C = \frac{n_c}{n_v} \times 100 \tag{51}$$

where, n_c represents the count of statements that are factually consistent and n_v represents the total count of the assessed statements. The higher the factual consistency, the better the educational performance is achieved.

For the trust assessment, the EdNet and OULAD datasets provide the context of learner interaction, assessment, and the educational process, but are not used as direct grounds for answers. The produced responses are scored against the ground-truth answers and corresponding educational question-answer information provided with the evaluated learning tasks, which serve as reference information for factuality and hallucination evaluation. The factual correctness is determined by factual statements extracted from the generated responses and compared to the reference information. In addition, the alignment to the curriculum is evaluated based on the target concept and learning objective of the given prompt. The hallucination probability is inferred from the response's unsupported or incorrect statements identified against the reference information. The confidence score is obtained from the model confidence assessment, while the explanation quality is based on the response's relevance, completeness, clarity, and overall consistency. Finally, the educational completeness is defined by the response's ability to fully incorporate the required elements of the given prompt.

3) Explainability

a) Explanation fidelity: It is generally used to measure the accuracy with which the obtained explanation reflects the

factors leading to an educational decision. It is expressed as follows,

$$E_F = \frac{n_c}{n_e} \times 100 \quad (52)$$

where, n_c represents the number of explanations that are consistent with the decision-making process and n_e represents the total number of explanations evaluated.

b) Explanation quality: It is generally used to estimate the explanation quality according to its relevance, completeness, clarity, and consistency. $E_Q = \frac{1}{n}\sum_{i=1}^{n} q_i$, where q_i represents the quality score of the explanation i, and n denotes the count of evaluated explanations.

c) User interpretability: it is used to assess learners' ability to understand and interpret the obtained explanations, which is expressed as $I_U = \frac{1}{n}\sum_{i=1}^{n} u_i$, where u_i represents the interpretability rating generated by the learner i, typically assessed using a Likert-scale evaluation, where higher scores demonstrate greater user interpretability.

For the purpose of explainability evaluation, the fidelity of the produced explanation to the factors that contributed to the corresponding educational decision is determined. Explanation quality is measured in terms of relevance, completeness, clarity, and consistency of the derived explanation. User interpretability is then derived from the learner-oriented interpretability metric as specified in the evaluation procedure. The evaluation is conducted using the same criteria and scoring process for all obtained explanations; hence, no separate expert-panel or multi-rater evaluation is necessary, and inter-rater reliability is not determined. The fidelity, explanation quality, and interpretability measures reported in the study are automated, criterion-based indicators designed to provide a consistent and reproducible assessment of generated explanations. They quantify properties such as consistency with the generated response, relevance, completeness, clarity, and alignment with the associated learning content. These measures are therefore intended as proxy indicators of explanation quality.

4) Efficiency

a) Inference latency: It is used to measure the average execution time taken by the model to generate an output, which is formulated as,

$$L_I = \frac{1}{n}\sum_{i=1}^{n} t_i \quad (53)$$

where, t_i represents the inference time for interaction i.

b) Memory consumption: It is used to measure the memory consumed by the model during execution. Therefore, low memory utilization indicates more effective utilization of system resources and supports placement in resource-constrained educational environments.

c) Number of model parameters: It is used to estimate the total number of trainable parameters of the LITE-Trust model, which reflects the memory consumption and model complexity, where a lower parameter count indicates that the model is lightweight.

d) FLOPs: It is used to evaluate the number of floating-point operations required during model inference, which reflects the computational complexity of the LITE-Trust architecture, while fewer FLOPs indicate lower computational complexity.

e) Computational cost: It is used to measure the computational burden of the system, with lower values indicating more computational efficiency and lighter algorithms.

f) Response time: It is used to compute the overall processing time taken from receiving the request from the user until the moment of providing the final response, which is defined as,

$$R_T = t_o - t_i \quad (54)$$

where, t_o, and t_i represent the request delivery, and request response times, respectively.

To improve the objectivity and reproducibility of the trust model, all trust components are determined using predefined evaluation criteria and are kept fixed across the experiments. Factual correctness and hallucination are evaluated against the corresponding ground-truth answers and educational reference information, while curriculum alignment is assessed with respect to the target concept and learning objective of each task. Confidence is obtained from the model's confidence assessment. Explanation quality is evaluated according to relevance, completeness, clarity, and consistency, whereas educational completeness reflects whether the required instructional elements of the task are adequately covered. These criteria are applied uniformly to all evaluated responses rather than being adjusted according to the obtained performance. The weights assigned to the individual trust components are fixed before the experimental evaluation and are applied identically to all datasets, learner profiles, and generated responses. The weight selection is based on the relative importance of factual reliability, instructional relevance, and response quality for educational recommendation. No weight is modified based on the performance of an individual model or test sample. This fixed-weight protocol prevents post-hoc adjustment of the trust score and improves reproducibility across experiments.

The reliability of the trust assessment is further examined by evaluating the individual trust components separately from the overall trust score. Factual consistency and hallucination rate are evaluated against reference educational information, while curriculum alignment and educational completeness are assessed against the predefined learning objectives and task requirements. Explanation quality is evaluated independently using its relevance, completeness, clarity, and consistency criteria. The component-level results are then compared with the aggregated trust score to verify that high trust values correspond to responses with stronger factual reliability, lower unsupported content, appropriate curriculum coverage, and better educational completeness.

To improve the reliability of the knowledge-gain evaluation, the pre-learning and post-learning assessments are compared under consistent learner and assessment conditions.

The same learner profiles, target concepts, assessment criteria, and evaluation protocol are maintained across the compared methods. Learner characteristics and prior knowledge are considered when interpreting the observed improvement, while temporal progression, repeated exposure, and differences in learner participation are controlled as far as permitted by the available data.

C. Overall Performance Comparison

The LITE-Trust is compared with existing approaches such as conventional ITS [15], conventional multi-agent systems [10], LLM-based tutoring [6], non-optimized multi-agent systems [12], optimization-based approach [20], and adaptive learning models [7], to evaluate its performance. These baselines were selected as they represent major paradigms of the educational system addressed by LITE-Trust, namely, rule-based tutoring, multi-agent coordination, LLM-assisted learning, adaptive learning modelling, and optimization-driven personalization. Each baseline is evaluated on the same EdNet and OULAD datasets, with the same train/test partitions, hardware configuration, and evaluation metrics as LITE-Trust, using comparable learner-level partitions of the data to ensure validity of comparison, with variations specific to each method and their implementation details retained.

For a fair comparison, all baseline methods and the proposed LITE-Trust framework were evaluated under the same experimental setting, including the same datasets, learner profiles, input information, evaluation protocol, and computing environment. The same experimental scenarios and stopping criteria were maintained for all methods. Each baseline was implemented using its defined methodological characteristics, while the proposed framework used the same available input and evaluation conditions. Model-specific parameters, prompts, and configuration settings were kept fixed within each method and were not selectively adjusted to favor the proposed approach. This ensures that the reported differences are primarily attributable to the methodological differences between the compared approaches rather than changes in the experimental conditions.

The results in Tables VIII–XV are presented as descriptive performance comparisons, with mean values and standard deviations used to indicate central performance and variability across experimental runs. Formal statistical testing was applied to the optimizer-level comparison because ELRA was specifically evaluated against alternative optimization strategies. Nevertheless, to strengthen the statistical reliability of the broader baseline comparisons, confidence intervals and/or appropriate pairwise statistical tests can additionally be reported for the headline metrics. Differences such as 95.6% versus 90.1% are interpreted as observed performance improvements rather than statistically significant differences unless supported by the corresponding statistical test.

TABLE VIII. ANALYSIS OF EDUCATIONAL PERFORMANCE ON EDNET AND OULAD DATASET

Model	EdNet			OULAD		
	KG (%)	Accuracy (%)	F1 (%)	KG (%)	Accuracy (%)	F1 (%)
Conventional ITS	12.7±0.5	85.5±0.5	85.8±0.5	11.9±0.6	85.1±0.5	85.1±0.5
Conventional multi-agent system	13.6±0.5	87.5±0.6	86.0±0.7	12.9±0.6	87.0±0.5	86.1±0.7
LLM-based tutoring	14.5±0.6	87.6±0.5	87.9±0.6	13.4±0.7	86.9±0.4	87.1±0.6
Non-optimized multi-agent system	15.2±0.4	89.1±0.5	88.7±0.5	14.2±0.6	88.8±0.6	88.3±0.6
Adaptive Learning model	15.3±0.7	89.2±05	89.2±0.5	14.5±0.5	88.9±0.6	88.3±0.5
Optimization-based approach	16.5±0.4	90.1±0.5	89.9±0.6	15.1±0.5	89.8±0.5	89.0±0.5
LITE-Trust	**18.8±0.5**	**95.6±0.2**	**94.5±0.4**	**17.9±0.4**	**94.8±0.3**	**93.5±0.4**

Table VIII explains the numerical results of educational performance on the EdNet and OULAD datasets. The LITE-Trust achieves the highest performance with an accuracy of 95.6%, an F1-score of 94.5%, knowledge gain of 18.8% on the EdNet dataset, and 94.8%, 93.5%, and 17.9% on OULAD, respectively. The optimization-based approaches achieve only 90.1% accuracy and 89.9% F1-score on EdNet, and 89.8% accuracy and 89.0% F1-Score on the OULAD dataset. This enhancement is obtained by integrating KSE-based concept-level knowledge estimation with ELRA-based educational optimization, which enables decisions to be modified to the learner's current knowledge and needs. Unlike existing approaches, which generally focus on a single capacity, such as tutoring, prediction, adaptation, multi-agent processing, or optimization, LITE-Trust collectively models learner state and optimizes personalized educational configurations. The reported results are expressed as mean ± standard deviation to indicate the performance variability across individual runs. For knowledge gain evaluation, the learner interactions in each learning episode are divided into temporally ordered pre-learning and post-learning windows relative to the personalized learning process. Specifically, the pre-learning window comprised the assessment interactions preceding the recommended learning process, whereas the post-learning window comprised the assessment interactions following it. Knowledge gain (KG) is calculated from the enhancement in mean assessment performance between these two windows. These results are gained from KSE-driven recommendations and ELRA-guided optimized agent coordination, which minimize redundant educational actions and enhance learner-specific resource selection.

Table IX explains the performance of trustworthiness on EdNet and OULAD datasets. The LITE-Trust system achieves 94.5%/93.8% trust, 3.1%/3.4% hallucination, and 96.4%/95.6% factual consistency, demonstrating superior performance compared with the existing approaches. This achievement was obtained by integrating student profile

construction, KSE, ELRA, personalized agent coordination, and trust verification, which preserves learner-specific, context-guided, and factually interpretable decisions. Existing approaches primarily focus on individual capabilities without integrating learner profiles with continuous trust evaluation, which results in lower trust and higher hallucination.

TABLE IX. ANALYSIS OF TRUSTWORTHINESS ON EDNET AND OULAD DATASET

Model	EdNet			OULAD		
	Trust (%)	Hallucination (%)	FC (%)	Trust (%)	Hallucination (%)	FC (%)
Conventional ITS	82.1±0.7	7.8±0.5	86.3±0.7	81.1±0.8	8.0±0.6	85.0±0.8
Conventional multi-agent system	82.9±0.8	7.5±0.5	86.7±0.7	81.8±0.8	7.8±0.5	86.1±0.7
LLM-based tutoring	84.5±0.8	7.0±0.5	88.2±0.6	83.6±0.9	7.3±0.5	86.9±0.7
Non-optimized multi-agent system	85.5±0.7	6.8±0.5	87.5±0.6	84.5±0.8	7.1±0.5	87.2±0.7
Adaptive Learning model	86.4±0.7	6.1±0.4	89.5±0.6	85.0±0.7	6.5±0.6	88.3±0.6
Optimization-based approach	87.1±0.6	5.9±0.4	89.8±0.5	86.1±0.7	6.3±0.6	89.1±0.6
LITE-Trust	**94.5±0.4**	**3.1±0.3**	**96.4±0.4**	**93.8±0.5**	**3.4±0.3**	**95.6±0.5**

TABLE X. ANALYSIS OF EXPLAINABILITY ON EDNET AND OULAD DATASET

Model	EdNet			OULAD		
	Fidelity (%)	Quality (%)	Interpretability (%)	Fidelity (%)	Quality (%)	Interpretability (%)
Conventional multi-agent system	80.5±0.8	79.3±0.9	76.9±0.7	79.8±0.7	78.5±0.7	76.2±0.8
Conventional ITS	82.3±0.7	80.6±0.8	78.7±1.0	81.6±0.9	79.8±0.8	77.8±0.8
Non-optimized multi-agent system	84.3±0.8	83.0±0.8	81.2±0.9	83.7±0.9	82.0±0.9	80.4±0.7
LLM-based tutoring	85.3±0.6	83.1±0.8	81.9±0.8	84.2±0.8	82.4±0.7	80.9±0.7
Optimization-based approach	86.5±0.7	84.5±0.8	83.4±0.8	85.1±0.8	84.2±0.9	82.3±0.8
Adaptive Learning model	86.9±0.7	85.6±0.7	84.1±0.8	85.8±0.8	85.0±0.8	83.5±0.6
LITE-Trust	**95.0**±0.4	**94.1**±0.5	**92.6**±0.5	**94.6**±0.5	**93.4**±0.5	**92.1**±0.5

Table X explains the explainability performance on EdNet and OULAD datasets. The LITE-Trust model achieves the highest fidelity of 95.0%/94.6%, explanation quality of 94.1%/93.4%, and interpretability of 92.6%/92.1% across two datasets. The highest results were achieved by implementing context-aware generation and validation of explanations, where the system combines learner-specific evidence and decision outputs before generating the final explanations. Subsequently, the produced explanations remain close to the decisions actually made and are detailed enough to be informative for the learners. In contrast, existing methods often generate generalized explanations with restricted alignment to the learner-specific personalized decisions, which leads to lower fidelity, quality of explanation, and interpretability.

TABLE XI. ANALYSIS OF COMPUTATIONAL EFFICIENCY ON EDNET AND OULAD DATASET

Model	EdNet			OULAD		
	Latency (ms)	Memory (MB)	Parameters (M)	Latency (ms)	Memory (MB)	Parameters (M)
Adaptive Learning model	16.3	92.5	2.19	17.4	93.4	2.19
Conventional ITS	17.4	95.4	2.71	18.2	98.2	2.71
Non-optimized multi-agent system	18.4	98.7	3.08	19.5	99.7	3.08
Optimization-based approach	19.4	109.5	3.75	19.8	110.1	3.75
Conventional multi-agent system	19.5	105.8	3.43	20.4	106.9	3.43
LLM-based tutoring	20.2	118.1	6.20	21.5	119.8	6.20
LITE-Trust	**10.5**	**80.5**	**1.92**	**9.5**	**81.3**	**1.92**

Table XI depicts the computational efficiency of proposed and existing approaches on the EdNet and OULAD datasets in terms of latency, memory usage, and parameter count. LITE-Trust achieves the lowest latency of 10.5 ms and 9.5 ms, memory usage of 80.5 MB and 81.3 MB, and parameter count of 1.92 M on EdNet and OULAD, respectively. Compared with existing methodologies, the proposed LITE-Trust system minimizes computational needs while preserving a lightweight architecture. The lowest latency demonstrates faster execution, while the reduced number of memory and parameters proves

the method's lightness. In addition, the similar results for different datasets signify that the efficiency of the LITE-Trust model is not tied to a particular dataset.

D. Earning Personalization Performance

Table XII illustrates the learning personalization performance of presented and existing works in terms of learner adaptation, knowledge-gap identification, recommendation accuracy, and learning-path quality. LITE-Trust system achieves the highest scores of 94.1%, 93.2%, 94.0%, and 92.9%, respectively. This enhancement is achieved by the combined effect of the presented approach, where the student profile construction extracts individual learner characteristics, KSE preserves the evolving knowledge state, ELRA improves learning configurations, and responsive multi-agent architecture allocates learner-specific instructional tasks. The explainability engine then evaluates and transfers the rationale behind the produced learning decisions, while the trust-based strategy makes recommendations for trustworthy educational information. Unlike existing approaches, which generally deploy less integrated personalization strategies and generate restricted coordination among learner profiling, knowledge evaluation, optimization, recommendation, and decision validation. Therefore, they are less efficient in adjusting to changing learner needs, identifying specific knowledge gaps, and constructing high-quality personalized learning paths.

TABLE XII. ANALYSIS OF LEARNING PERSONALIZATION PERFORMANCE

Model	Learner Adaptation (%)	Knowledge Gap Identification (%)	Recommendation Accuracy (%)	Learning Path Quality (%)
LLM-based tutoring	81.2±0.7	79.9±0.8	80.5±0.7	78.7±0.8
Conventional multi-agent system	83.6±0.6	81.6±0.7	82.7±0.6	80.6±0.7
Conventional ITS	84.5±0.7	82.6±0.7	83.9±0.7	81.7±0.9
Non-optimized multi-agent system	85.3±0.6	83.4±0.6	84.2±0.6	82.6±0.7
Adaptive Learning model	86.4±0.5	84.2±0.7	85.1±0.7	83.4±0.6
Optimization-based approach	87.2±0.5	85.7±0.6	86.7±0.6	84.7±0.6
LITE-Trust	**94.1**±0.4	**93.2**±0.5	**94.0**±0.4	**92.9**±0.5

E. Trust and Hallucination Analysis

Table XIII depicts the trust and hallucination analysis of the proposed and existing approaches. The LITE-Trust model achieves the highest trust of 94.15% and hallucination reduction of 54.6%, which demonstrates the enhanced reliability of the produced educational outcomes. The overall trust score is calculated as the average of the dataset-specific trust scores obtained on EdNet and OULAD. The hallucination reduction values are calculated using Eq. (33), with the LLM-based tutoring approach as the baseline. The results show a gradual improvement in hallucination reduction from the LLM-based tutoring method to the conventional multi-agent, conventional ITS, non-optimized multi-agent, adaptive learning, and optimization-based approaches, while LITE-Trust achieves the highest reduction.

TABLE XIII. TRUST AND HALLUCINATION ANALYSIS

Model	Trust Score (%)	Hallucination Reduction (%)
LLM-based tutoring	80.8±0.9	18.6±0.8
Conventional multi-agent system	82.5±0.8	22.5±0.8
Conventional ITS	83.7±0.7	25.3±0.7
Non-optimized multi-agent system	84.9±0.6	29.3±0.8
Adaptive Learning model	85.8±0.6	34.8±0.7
Optimization-based approach	86.8±0.5	39.8±0.6
LITE-Trust	**94.15±0.4**	**54.6±0.5**

The enhancement is qualified by the incorporation of student profile construction, KSE, ELRA, personalized multi-agent coordination, explainability engine, and trust-based validation approaches. These subsystems jointly support learner-specific decision generation, evidence-based recommendations, explanation evaluation, and controlled response generation. In contrast, the existing methods generally provide relatively restricted strategies for collectively evaluating generated content, learner-specific decisions, and explanatory consistency. The higher hallucination reduction achieved by LITE-Trust therefore indicates improved control of potentially unsupported responses, contributing to higher overall trust in the generated educational outcomes.

F. Explainability Analysis

Table XIV presents the explainability performance of the proposed and existing approaches in terms of quality and transparency. Table XV represents the examples of

explanations and recommendations. The LITE-Trust model achieves superior performance of 94.1% explanation quality and 93.8% transparency, which shows that it provides informative and transparent explanations to the learner. The quality of the explanations and the transparency of the recommendations in the explanations were assessed using an automated scoring protocol. The explanations were scored and compared based on relevance, adequacy, clarity, consistency, and correspondence with the recommendation. For each explanation, scores were calculated based on these criteria and converted into percentages for comparison between the recommendation models. Additionally, the qualitative examples demonstrate that LITE-Trust is able to link the learner context to the recommended learning resources along with presenting an explanation for the recommendation outputs. This is made possible due to the combination of comprehensive learner profiling, knowledge-state representation, ELRA-based decision optimization, adaptive multi-agent coordination, and explainability engine mechanisms, which together facilitate exposing the recommendation factors. On the other hand, the compared solutions provide only the recommendation output with little information about the factors influencing the outcome, thus being less transparent and informative in terms of explanation.

To ensure objective evaluation, fidelity, explanation quality, and interpretability are calculated using predefined evaluation criteria applied consistently across all generated responses. Fidelity measures the extent to which the explanation accurately reflects the evidence and reasoning associated with the generated response. Explanation quality evaluates relevance, completeness, clarity, and consistency of the explanation, while interpretability assesses whether the explanation can be readily understood and traced to the corresponding learning content and response. The evaluation criteria and scoring procedure are kept fixed across all experiments to avoid subjective variation. The reported percentages represent normalized scores aggregated across the evaluated responses. No post-hoc adjustment of scores is performed based on the obtained results. Where human evaluation is included, responses are independently assessed using the same predefined criteria by the designated evaluators, and the final score is obtained from their assessments.

TABLE XIV. EXPLAINABILITY ANALYSIS

Model	Explanation Quality (%)	Transparency (%)
LLM-based tutoring	80.5±0.7	79.6±0.7
Conventional multi-agent system	82.0±0.6	81.4±0.7
Conventional ITS	84.5±0.7	82.8±0.8
Non-optimized multi-agent system	85.6±0.6	84.7±0.7
Adaptive Learning model	86.9±0.5	85.4±0.6
Optimization-based approach	87.5±0.5	86.1±0.6
LITE-Trust	**94.1±0.4**	**93.8±0.5**

TABLE XV. EXAMPLE OF RECOMMENDATION AND EXPLANATIONS

Student Context	Recommendation	Generated Explanation
Low performance in algebra; good performance in arithmetic, fair performance in equations	Intermediate algebra learning resource	The learner is adequately proficient in arithmetic, but lacks knowledge in solving equations. Hence, it is recommended to study intermediate algebra to improve equation-solving skills
Poor understanding of probability, moderate performance in statistics fundamentals	Probability learning resource-intermediate level	The learner lacks an adequate understanding of the idea of probability. The recommended module was chosen based on the learner's current knowledge and the identified learning needs.

G. Lightweight Performance Analysis

Table XVI depicts the existing non-optimized multi-agent method with the full-agent, selective multi-agent, and overall LITE-Trust configurations. The evaluation in Table XVI is conducted on the OULAD dataset for the learner outcome prediction task. Full-agent LITE-Trust has more overhead since all agents are activated, while selective activation only triggers relevant agents according to educational requirements. The parameter counts presented in Table XVI relate only to the trainable parameters in the proposed LITE-Trust components, while the external GPT-4o mini model remains constant across all configurations of LITE-Trust. The difference between 2.46M and 3.35M in the full-agent configuration stems from the activation of all task-specific agents and their corresponding processing layers. In the selective multi-agent configuration, only the agents relevant to the specified requirements are engaged, thus accounting for a lower count of trainable parameters at 2.46 M. The overall LITE-Trust configuration further decreases the parameter count to 1.92 M due to parameter sharing and the elimination of task-specific components within the integrated pipeline. Therefore, the variation in parameter counts originates from the proposed configurations rather than the external large language model. The 94.8% accuracy reported for the overall LITE-Trust configuration corresponds to the OULAD-specific result in Table VIII, whereas the 95.6% accuracy in Table VIII represents the separate EdNet evaluation.

TABLE XVI. LIGHTWEIGHT PERFORMANCE ANALYSIS

Method	Parameters (M) ↓	Latency (ms) ↓	Memory (MB) ↓	Accuracy (%) ↑
Non-optimized multi-agent system	3.08	18.4	98.7	88.7
Full multi-agent LITE-Trust	3.35	16.9	102.1	95.4
Selective multi-agent LITE-Trust	2.46	11.7	89.5	95.2
Overall LITE-Trust	**1.92**	**9.5**	**81.3**	**94.8**

The reported 1.92 M parameters represent only the locally implemented components of the proposed framework and exclude the externally accessed GPT-4o mini and embedding model. Therefore, the parameter count should not be interpreted as the complete deployed-system size. To provide a more realistic assessment of lightweight deployment, the evaluation considers end-to-end factors including local computational resources, API response latency, network communication overhead, external inference cost, and memory usage. The framework is therefore characterized as lightweight primarily with respect to its locally deployed components and selective agent execution, rather than as a parameter-light representation of the entire external AI service stack.

The overall LITE-Trust reduces computational costs by several means, such as compact learner and knowledge-state representations, limited ELRA search, selective agent activation, and efficient algorithms for processing explanations and trust. Selective agent activation contributes to efficiency by reducing unnecessary agent execution; however, the overall end-to-end enhancement cannot be attributed solely to reducing the number of active agents. Instead, the results indicate the agent-level reduction works together with the optimization of the complete pipeline, such as KSE, ELRA, retrieval, trust, and XAI processing. Therefore, selective activation provides an important agent-level efficiency benefit, while the overall lightweight performance results from the combined optimization of the entire LITE-Trust pipeline.

H. ELRA Optimization Performance

To ensure consistency in comparison, GA, PSO, ACO, LRA, and ELRA have been evaluated using the same population size, equal to 30, the same learner-specific fitness function, and the same experimental scenario with five independent runs using random seeds 11, 22, 33, 44, and 55. The value of 30 is selected for population size on the basis of the performed sensitivity analysis to balance the solution quality and computational effort. All the configurations used in the experiments can be considered reasonable as they conform to standard educational performance measures and use the specific search and update mechanisms of the respective algorithms.

Table XVII depicts the comparison of the proposed and conventional optimization algorithms, namely GA, PSO, ACO, and LRA, in terms of convergence, fitness, standard deviation, computational time, agent activation, and learning performance. ELRA achieves faster convergence, higher fitness, the lowest standard deviation, lower computational time, fewer activated agents, and the best learning performance among the compared optimizers. The lowest standard deviation means high consistency of the results of independent runs. These advantages were achieved due to ELRA's learner-state-guided initialisation, constrained candidate generation and relevance-based optimization, and quality-and diversity-based selection, which aims to facilitate optimization by focusing the search on promising learner-specific configurations and avoiding redundant exploration. The overall comparison among five optimizers was statistically significant based on the Friedman test ($p \approx 0.001$), which indicates significant differences in optimizer performance across the evaluated methods.

The direct comparison with conventional LRA further demonstrates the contribution of the ELRA modifications. Under the same population size, learner-specific fitness function, experimental scenario, and independent random seeds, ELRA improves the best fitness from 0.89 obtained by LRA to 0.93, corresponding to a relative improvement of approximately 4.5%. ELRA also reduces convergence iterations from 38 to 28 (26.3% reduction), standard deviation from 0.025 to 0.012 (52.0% reduction), computational time from 15.4 ms to 10.8 ms (29.9% reduction), and average activated agents from 3.9 to 2.7 (30.8% reduction). Learning performance increases from 91.2% to 94.8%, an absolute improvement of 3.6 percentage points. These results indicate that the learner-state conditioning, trust-aware candidate filtering, and relevance-based search mechanisms provide measurable benefits beyond the conventional LRA search strategy.

TABLE XVII. ELRA OPTIMIZATION PERFORMANCE

Optimizer	Convergence iterations ↓	Best Fitness ↑	Standard Deviations ↓	Computational Time (ms) ↓	Activated Agents ↓	Learning Performance (%) ↑
GA	50	0.86	0.035	21.5	4.8	89.5
PSO	47	0.87	0.031	18.9	4.6	89.6
ACO	44	0.88	0.029	17.8	4.2	90.5
LRA	38	0.89	0.025	15.4	3.9	91.2
ELRA	**28**	**0.93**	**0.012**	**10.8**	**2.7**	**94.8**

I. Ablation Study

Table XVIII depicts the ablation study results, which highlight the contributions made by each component of the proposed LITE-Trust. Excluding ELRA reduces the learning pathway quality from 94.8% to 89.5% since the learner's KSE is not transformed into an optimized learning configuration, resulting in lower resource and path utility. This confirms ELRA's role in converting learner-state information into personalized educational configurations. Excluding the trust engine lowers trust by 9.8% because the produced recommendations are no longer validated against the reliable educational information repository via the trust-aware validation mechanism. This degradation reflects the role of trust evaluation in improving the reliability of educational decisions. Removing the explainability engine decreases the explanation quality from 94.6% to 78.3%, representing a 16.3% reduction, while slightly reducing latency from 9.5 ms to 8.8 ms. This trade-off is expected because removing XAI eliminates explanation-processing overhead but reduces transparency and interpretability. Excluding dynamic agent selection increases the latency from 9.5 ms to 16.5 ms, representing a 73.7% increase, because unwanted agents are activated instead of directly employing only the relevant agents. These results demonstrate that LITE-Trust balances multiple objectives rather than maximizing every metric simultaneously, with XAI improving interpretability and agent selection enhancing computational efficiency. Finally, the overall performance of the complete LITE-Trust achieves 94.8% accuracy, 95.2% trust score, 94.6% XAI quality, 9.5 ms latency, and 94.8% learning path quality, since the student profile construction accurately represents the learners' features. KSE maintains the required knowledge state, ELRA determines the best configuration, dynamic coordination activates only necessary agents, and the trust and XAI engine enhance the transparency of decisions and recommendations. Therefore, the observed degradation after removing each component is consistent with its intended function, which confirms the complementary contribution of ELRA, trust evaluation, XAI, and dynamic agent selection to personalized, reliable, transparent, and efficient learning.

TABLE XVIII. ABLATION STUDY OF LITE-TRUST SYSTEM

Model	Accuracy (%)	Trust Score (%)	XAI Quality (%)	Latency (ms)	Learning-path Quality (%)
Model A: without ELRA	91.7	92.5	91.6	14.3	89.5
Model B: Without Trust Engine	93.8	85.4	91.9	9.7	93.0
Model C: Without XAI	94.0	94.2	78.3	8.8	93.6
Model D: Without Agent Selection	94.2	94.0	93.6	16.5	94.1
Model E: Overall LITE-Trust	**94.8**	**95.2**	**94.6**	**9.5**	**94.8**

To further clarify the contribution of individual modules, the ablation analysis is organized as controlled component-wise comparisons. Each variant removes one module while keeping the dataset, learner profiles, experimental conditions, and remaining framework components unchanged; changes in accuracy, trust, explainability, latency, and learning-path quality are compared with the complete model. The resulting LITE-Trust framework. This analysis identifies the principal contribution of each component while minimizing the influence of changes in other experimental factors. The observed improvements are interpreted as component-level contributions; interaction effects among multiple modules are considered a limitation of the current ablation design and are not claimed as independently established causal effects.

J. Sensitivity and Convergence Analysis

Table XIX shows that increasing the population size from 10 to 30 raises the fitness from 0.90 to 0.93 and the learning performance from 92.2% to 94.8%, while further increasing it to 40 provides only a marginal improvement to 94.9%. Similarly, increasing the number of iterations beyond 0 provides only marginal improvement in learning performance. Therefore, the selected configuration represents a performance-efficiency trade-off, where a population size of 30 and 60 iterations provides nearly the same performance as larger configurations while avoiding additional computational cost. Thus, the balanced configuration was optimized for both educational effectiveness and computational performance, which reached the maximum fitness of 0.93 and a learning performance of 94.8%. These results suggest that ELRA is fairly robust to parameter variations, as moderate changes to the population size and iteration number affected the outcomes within a reasonable range. More importantly, population size, iteration number, and by extension, the optimization process itself are predefined computational constraints, not learner-specific variables. Hence, while ELRA extends the lightweight optimization principles of LRA, its educational adaptation introduces a restricted set of control parameters to control optimization and agent activation, while retaining the lightweight optimization philosophy of the original LRA. The weighting strategy is assessed using sensitivity analysis. Table XX below compares the trust, efficiency, learning, and balanced configuration based on attained fitness and learning performance. It can be seen that the balanced configuration had the highest fitness score of 0.93 and the best learning performance of 94.8% and was thus selected as the final ELRA configuration.

To examine whether the selected threshold values are robust, a sensitivity analysis is performed by varying the trust threshold and agent activation threshold across multiple levels while keeping the remaining experimental settings unchanged. The evaluation considers hallucination rate, response quality, agent utilization, latency, and learner performance. The same datasets, learner profiles, prompts, agent pool, and evaluation procedure are maintained for each threshold setting so that the

observed differences can be attributed primarily to threshold variation.

TABLE XIX. SENSITIVITY AND CONVERGENCE ANALYSIS

Parameter	Setting	Convergence iterations ↓	Fitness ↑	Learning performance (%) ↑
Population size	10	33	0.90	92.2
	20	29	0.92	93.7
	30	**27**	**0.93**	**94.8**
	40	27	0.93	94.9
Iterations	20	34	0.89	92.5
	40	29	0.91	94.1
	60	**27**	**0.93**	**94.8**
	80	26	0.92	94.9

TABLE XX. SENSITIVITY ANALYSIS OF ELRA WEIGHTING CONFIGURATIONS

Weighting Configuration	Trust	Efficiency	Learning	Fitness ↑	Learning Performance (%) ↑
Trust-based	0.49	0.20	0.30	0.88	92.5
Efficiency-based	0.20	0.49	0.30	0.89	92.8
Learning-based	0.20	0.29	0.49	0.90	93.4
Balanced	**0.33**	**0.33**	**0.34**	**0.93**	**94.8**

TABLE XXI. STATISTICAL JUSTIFICATION OF THE ELRA AGAINST THE GA, PSO, ACO, AND LRA

Trust threshold	Hallucination rate (%)	Response quality (%)	Agent utilization (%)	Latency (ms) ↓	Learner performance (%)
0.50	7.20	91.40	92.50	182	92.10
0.60	6.10	92.80	89.70	190	93.00
0.70	4.90	94.20	86.30	199	94.10
0.80	3.80	95.60	82.10	211	95.00
0.90	2.90	96.70	76.80	228	95.40

The threshold sensitivity results demonstrate the effect of threshold selection on the reliability and efficiency of the proposed framework. Lower thresholds allow more candidate responses and agents to participate, which can increase agent utilization and potentially reduce computational filtering, but may also permit less reliable responses to proceed. In contrast, higher thresholds impose stricter trust and activation requirements, which can reduce unnecessary agent execution and unsupported responses but may also reject useful responses or increase processing overhead associated with additional validation. The intermediate threshold setting provides a balanced operating point when considering hallucination control, response quality, agent utilization, latency, and learner performance.

K. Statistical Significance Analysis

Table XXI depicts the statistical justification of the ELRA against the GA, PSO, ACO, and LRA. The statistical unit is an independent experimental run, with five runs conducted using seeds 11,22,33,44,55. Learner interactions and independent optimization evaluation are not treated as independent samples. The Friedman test reveals that there are significant differences between the five optimizers used ($x^2 \approx 18.65$, $p \approx 0.001$). The exact two-sided Wilcoxon signed-rank test is applied to the five paired run-level results, yielding $p \approx 0.063$ for the pairwise comparisons. The Nemenyi post-hoc analysis is based on the same five-run rank matrix. The effect sizes vary from 0.64 to 0.83, suggesting that the improvements are substantial. In addition, the 95% confidence interval 0.91-0.93 reflects the stability of ELRA fitness across the five runs. Thus, the statistical analysis uses run-level statistical units and avoids treating correlated learner or interaction observations as independent samples.

TABLE XXII. ANALYSIS OF STATISTICAL SIGNIFICANCE

Metrics	ELRA Evaluation	Result
Statistical unit	Independent experimental runs	5 runs (seeds 11,22,33,44,55)
Friedman test	Overall difference among GA, PSO, ACO, LRA, and ELRA	$x^2(4) \approx 18.65$, $p \approx 0.001$
Wilcoxon signed-rank	ELRA vs. GA/PSO/ACO/LRA	$p \approx 0.063$
Nemenyi post-hoc	ELRA vs. GA/PSO/ACO/LRA	$p > 0.05$
Effect size	ELRA vs. GA/PSO/ACO/LRA	0.83/0.79/0.71/0.64
95% Confidence Interval	ELRA Fitness	0.91-0.93

The statistical results have been clarified to avoid overstating significance (Table XXII). Although ELRA shows better mean performance than the compared optimizers, the pairwise Wilcoxon result of approximately 0.063 and the Nemenyi results above 0.05 do not demonstrate statistically significant superiority at the conventional 0.05 level. Therefore, ELRA is described as showing better observed performance and practical improvement, rather than statistically significant superiority in every pairwise comparison. The overall statistical analysis is interpreted together with effect sizes, confidence intervals, variability across independent runs, and mean performance to provide a more complete assessment of the observed differences.

L. Discussion

The results indicate that the improvements of LITE-Trust come from the complementary interaction of its proposed components, as further enabled by the ablation study; removing any individual module consistently degraded the corresponding performance metrics. ELRA enhances agent selection by leveraging the learner profile and KSE to determine the optimal learning configuration and identify relevant agents, thus restricting the optimization search to the learner-relevant educational configurations and avoiding unwanted exploration of unsuitable learning paths. Moreover, KSE identifies concept-level knowledge gaps and prerequisite mastery, which enables ELRA to allocate learning resources and educational agents based on the learner's actual learning requirements instead of depending on aggregate performance indicators. Trust Evaluation boosts performance by ensuring the factual

consistency of the results through confirming AI-generated educational content before delivery, thus minimizing the inclusion of unsubstantiated information and enhancing the reliability of educational recommendations. Dynamic orchestration facilitates reduced computational costs by limiting the engagement to necessary agents for each learning task, thereby avoiding unwanted agent invocations, which reduces inter-agent communication complexity and lowers processing time and memory consumption. This offers a favourable balance between learning performance and computational demands, as LITE-Trust performs better than all the baseline methods at a lower cost than multi-agent and optimization-based methods. The ablation results further indicate that the combined operation of KSE, ELRA, trust evaluation, explainability, and selective multi-agent orchestration generates more benefits than employing these components individually, which highlights their complementary contributions to personalization, optimization, trustworthiness, explainability, and computational efficiency. In comparison to the existing educational AI methods, which mostly focus on personalization, multi-agent orchestration, optimization techniques, explainability, or trust, LITE-Trust provides an integrated learner-centric approach that combines personalization, orchestration of multiple agents, optimization, explainability, and trust evaluation. In practice, such reduced complexity and selectivity would be critical to support the implementation in contexts where computational resources are limited, but learning personalization, performance, explanation, and trust are needed.

M. Limitations and Future Directions

Although LITE-Trust has shown promising results, there are still several limitations in terms of the current research. Firstly, it should be noted that it is based on a few educational benchmarks, making its ability to generalize questionable. Moreover, there was not enough practical application in a classroom setting, and using these lightweight GenAI components may lead to massive computational overhead. Then, it is hard to quantify the amount of learning gained by students since short-term gains do not always reflect long-term ones. Lastly, automatic trust and hallucination scores may miss many of the nuanced errors in natural language instruction.

The future directions of the research will address these concerns and explore different aspects of educational AI. In particular, they will focus on multimodal learning through speech, imagery, and behavioural data, and instruction via speech and vision. Federated educational AI and edge models will also be used to achieve better privacy and lighter computational needs while building more autonomous agents for education. Furthermore, future research will focus on longitudinal student modeling to understand learning gains better.

V. CONCLUSION

This study addressed the limitation of existing educational AI systems to provide personalized, optimized, trustworthy, explainable, and computationally efficient learning support. The LITE-Trust system integrated student profile construction, KSE, ELRA, dynamic multi-agent orchestration, explainability engine, and trust evaluation into a learner-centric pipeline. First, ELRA enhanced learner-specific educational configurations by leveraging the learner profile and KSE to focus the optimization search on relevant learning paths, resources, and agent configurations while avoiding superfluous optimization steps and agent exploration. Second, the trust-aware and explainable mechanisms improved the measured trust and explanation quality of produced educational outcomes by validating educational information and providing learner-specific rationales. Third, the lightweight multi-agent orchestration mechanism exploited relevance-based selective agent invocations to prevent superfluous agent executions, thereby reducing the measured computational overhead and response latency.

In addition, the behaviour-based academic integrity analyzer complemented the framework by estimating indicators related to academic integrity and AI usage based on learners' interactions, thus providing educators with valuable information without actually measuring these variables directly. Overall, the experimental results demonstrated that the LITE-Trust system achieved higher measured personalization, trust, explainability, and computational efficiency over the compared baseline methods. The ELRA analysis revealed faster convergence, higher fitness, stable optimization, and fewer agent invocations, while the ablation and statistical tests highlighted the complementarity of the integrated components. Thus, the designed approach demonstrated the effectiveness of a combined learner-state modeling, educational optimization, selective multi-agent orchestration, explainability, and trust validation pipeline for the estimated educational learning scenarios. However, the evaluation is limited to the EdNet and OULAD benchmark datasets, and trust assessment is performed through an automated framework-based mechanism rather than long-term human validation. Furthermore, due to the absence of ground-truth labels in the data concerning academic integrity and reliance on AI, the results of the academic integrity analyzer should be regarded as behavioural estimates rather than measurements. Large-scale real-world classroom deployment and comprehensive learner satisfaction measurement were not conducted. These aspects remain important directions for future evaluation.

ACKNOWLEDGMENT

The authors are thankful to the Deanship of Scientific Research, Vice Presidency for Graduate Studies and Scientific Research, King Faisal University, and Al-Fayha Private College, Jubail, Saudi Arabia, for providing financial assistance.

DATA AVAILABILITY

The datasets used and/or analyzed during the current study are available in the Kaggle repository, https://www.kaggle.com/datasets/anlgrbz/student-demographics-online-education-dataoulad and

https://www.kaggle.com/datasets/anhtu96/ednet-kt34. The datasets were obtained from their respective publicly accessible sources and used in accordance with their applicable terms of use and data-access policies. The datasets support the learner interaction, assessment, activity, and knowledge-estimation analyses reported in this study. The data used for the experiments are available from the corresponding public dataset repositories.

DECLARATIONS

Ethics Approval and Consent to Participate: This study used publicly available educational learning analytics datasets, namely the Open University Learning Analytics Dataset (OULAD) and EdNet. No participants were directly recruited or contacted by the authors, and no new personally identifiable information was collected for this study. The analyses were conducted on the datasets as provided by their respective sources and in accordance with the applicable terms of use and data-access requirements. Therefore, no additional participant recruitment or consent procedures were undertaken by the authors.

***Abstract*—In the modern Indian economy, agriculture is the most vital sector. Agriculture is an important source of revenue for the majority of the population of the world. Proper management of crops, crop species, crop field conditions, livestock, etc., can improve agricultural systems. The four primary subcategories of crop management are crop yield production management, weed management, crop disease management, and crop quality management. Planning agriculture, utilizing resources, and satisfying demand to ensure food security depend on accurate crop yield estimation. Crop yields are heavily influenced by climatic features like solar radiation, wind speed, rainfall, temperature, etc. Traditionally, crop yield management was completely performed by the farmers based on their experience using various techniques like crop rotation, mixed cropping, timely growing of crops, etc. These methods are combined with modern technologies like Artificial Intelligence, Internet of Things, drones, precision agriculture, etc., to improve crop productivity while considering preservation of natural resources. This study performed crop yield prediction using four baseline models based on machine learning: Decision Tree, Multiple Linear Regression, Support Vector Regression, and Random Forest. One of the best baseline models is further improved using nature-inspired algorithms. Four nature-inspired optimization algorithms used are: Whale Optimization Algorithm, Harris Hawks Optimization, Particle Swarm Optimization, and Grey Wolf Optimization. Particle Swarm Optimization-based optimized RF performed the best with R^2=98.32, MAE=9.2766.**

***Keywords*—Crop yield prediction; impact of climate change; decision tree; support vector regression; linear regression and random forest; particle swarm optimization; whale optimization algorithm; Harris Hawks optimization; grey wolf optimization**

I. Introduction

Climate change is an important challenge that impacts various living beings and our environment directly or indirectly. Continuous change in climate and the rise of CO2 concentration in our environment are making agricultural system enhancement more challenging [1]. The Food and Agriculture Organization (FAO) reports that there has been a sharp rise in grain consumption and demand as compared to crop production. From 1964 to 2030, the demand for rice, wheat, and other coarse grains increased steadily [2].

In agriculture, food security is highly threatened by climate change, as this change affects crop production. The impact of climate change on agriculture includes sudden increases or decreases in temperature, variable precipitation patterns, and a rise in the frequency of weather events [3][4]. In the agricultural sector, weather forecasting affects when crops are planted, harvested, and irrigated. This eventually helps to maximize crop yields and ensures food security [5]. Estimating crop production is a crucial component that depends on a number of variables, like soil characteristics, climate, and irrigation [6].

In the traditional crop assessment system, assessing soil health, crop growth, crop yield prediction, crop field management, etc. was done through manual observations, agricultural surveys, or by agricultural experts. However, wrong assessment led to reduced crop production. Numerous mitigating techniques have been employed over the past few decades, but the environment is still changing. Predicting crop yield is a challenge in modern precision agriculture, despite the proposal of numerous efficient models [7]. These models depict how temperature and precipitation variations directly impact crop production due to climate change.

The improvement of agricultural systems is greatly aided by Machine Learning (ML) approaches. ML is a scientific field that enables machines to learn without explicit programming [8]. Agriculture is increasingly using machine learning techniques to track and forecast environmental variables [9]. Numerous ML-based models have been proposed for agricultural system improvement [10]. However, managing massive volumes of data for precise conclusions and identifying the most significant climatic characteristics are the primary areas of worry. This can be resolved by employing an effective method that can also improve forecast performance.

In order to create more intelligent, quicker, and flexible systems, software engineers are increasingly using these natural designs. We refer to this method as "nature-inspired algorithms." It entails researching how organisms act, such as how ants locate food, how the brain learns, and how ecosystems maintain equilibrium, and then transforming those behaviours into functional software solutions. In order to solve open-ended problems, nature-inspired optimization strategies are both necessary and beneficial. Researchers and academicians can pursue a variety of avenues by comprehending nature-inspired methods and their significance for resolving practical issues.

A model for predicting agricultural crop yield while taking weather conditions into account has been proposed in this

*Corresponding author.

research. The following is the planned work's primary contribution:

- A complete data-analytic-based framework is created using existing algorithms for prediction of crop yield based on the impact of climate change through nature-inspired optimizing algorithms. The framework establishes how climate and agricultural variables can be incorporated into crop-yield prediction.
- Feature selection is performed using the RF approach.
- Crop yield prediction is performed using Multiple Linear Regression (MLR), Decision Tree (DT), Support Vector Regression (SVR), and Random Forest (RF) baseline models.
- The RF model is optimized using Particle Swarm Optimization (PSO), Whale Optimization Algorithm (WOA), Harris Hawks Optimization (HHO), and Grey Wolf Optimization (GWO) to predict crop yield.

This study's remaining sections are arranged as follows: Section II illustrates literature related to the proposed model. The suggested Crop Yield Prediction technique is briefly described in Section III. Section IV illustrates evaluation metrics used for comparison. Section V illustrates results and discussion. In Section VI, the entire study project is finally concluded.

II. Related Works

Numerous studies have been done in this field, which include identifying the best crop(s) and predicting crop yields using weather and soil information. Different articles related to the proposed work are summarized as follows:

Ramesh et al. [11] performed crop yield prediction using Neural Network (NN), Convolutional Neural Network (CNN), Long Short-Term Memory (LSTM), Recurrent Neural Network (RNN), and Deep Neural Network (DNN) and proposed a hybrid model that combines DNN with WOA and Adaptive PSO, which performed better than the other models. Mohanty et al. [12] performed rice yield forecasting at the district level in Odisha using MLR and Quantile Regression (QR) as base models and proposed a hybrid model that merges RF, eXtreme Gradient Boosting (XGBoost), and Artificial Neural Networks (ANN) models based on crop and climate data of Odisha. Chaurasia et al. [13] proposed a hybrid model that combines LR, Support Vector Machines (SVM), k-Nearest Neighbors (kNNs), DT, RF, and XGBoost based on ensemble learning for crop yield forecasting.

Manjunath et al. [14] performed crop yield prediction using Random Forest (RF), XGBoost, Decision Tree (DT), SVM, and Linear Regression (LR) and then merged the three best of these models using the ensemble learning (Voting) technique and concluded that the hybrid model performed better. Dehghanisanij et al. [15] proposed a hybrid model that uses Adaptive Neuro-Fuzzy Inference System (ANFIS) and the Seasons Optimization (SO) algorithm to estimate water-use efficiency and yield in apple orchards. Cao et al. [16] performed wheat yield prediction at country level and field level using traditional models: RF and three deep learning-based models: Deep Neural Networks (DNN), 1D Convolutional Neural Networks (1D-CNN), and Long Short-Term Memory (LSTM) model, and concluded that all four models performed well at country-level prediction, whereas DNN and RF performed too well at field-level prediction.

Khaki et al. [17] performed crop yield prediction of corn and soybean based on archived yield data, climate data, and soil data using a hybrid model that combines Convolutional Neural Network and Recurrent Neural Network (CNN-RNN). Han et al. [18] performed wheat yield prediction based on Climate, soil, vegetation index, cropland, and crop yield data using SVM, Gaussian process regression (GPR), RF, DT, NN, k-NN, boosted trees, and bagging trees, and concluded that SVM, RF, and GPR performed better than the other models. Sun et al. [19] proposed a hybrid model, CNN-LSTM, for prediction of Soybean yield based on past yield data, climate data, and Moderate Resolution Imaging Spectroradiometer (MODIS) data. Gopal et al. [20] proposed a hybrid model, MLR-ANN, to predict paddy yield based on Cropland, climate, soil, and past yield data. Hilal et al. [21] performed yield prediction of palm oil based on past yield data, cropland data, climatic data, and air pollutants data using Genetic algorithm/correlation analysis (GA/CA).

Sánchez et al. [22] performed crop yield prediction of multiple crops using Multiple linear regression, M5-Prime regression trees, perceptron multilayer neural networks, and concluded that M5-Prime and k-nearest neighbors performed better than other algorithms. To effectively predict agricultural productivity, it is crucial to observe climate patterns during sowing, the growing season, and throughout the year [23]. It is very difficult to accurately anticipate the crop growth stage using climate data because of very complicated dynamics that result in considerable changes in climatic factors [24]. Deep models used in [11], [17], [19], etc. have hidden parameter interactions. Stacking or voting architectures used in [12], [13], [14], etc. combine powerful baseline models but leave their hyperparameters fixed or unoptimized. In order to mitigate these concerns, this study has proposed an effective crop yield prediction model using RF optimization.

III. Methodology

Crop yield prediction while considering climate change is one of the important challenges in agriculture as climatic variables are fluctuating with respect to time. We depend on it to ensure food security and fulfill the future's food demand so as to accommodate the increase in the world's population of our world.

Fig. 1 depicts the methodology used for crop yield prediction. The proposed model is suitable for better prediction of yield, which can be used to increase crop yield production to fulfil future food demand. The model takes data related to crops and climate as an input. The input dataset is preprocessed by removing irrelevant columns and duplicate values. Then it is split into training data and Test Data. After splitting, One-Hot Encoding and normalization are performed in order to improve the classification accuracy. Following that RF based features selection is performed. The next step is to train the model using four machine learning baseline models: DT, MLR, SVR, RF and crop yield prediction is performed. Out of these four baseline

models, the best model is selected for further improvement using nature-inspired algorithms. Four RF optimized models: PSO optimized RF; WOA optimized RF; HHO optimized RF; and GWO optimized RF are trained and crop yield prediction is performed. The proposed model is explained as follows:

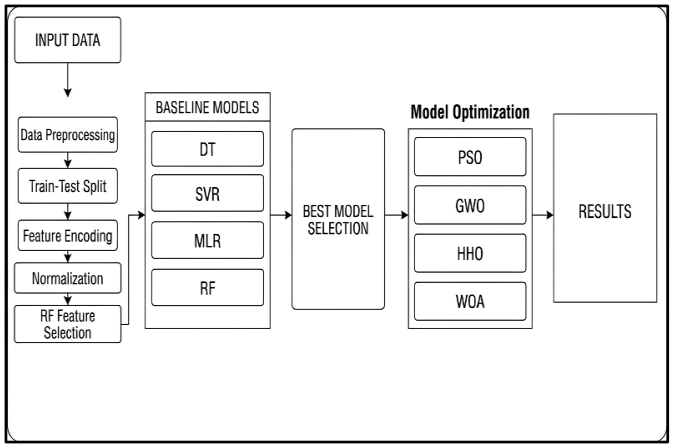

Fig. 1. The proposed model for crop yield prediction.

A. Crop and Climate Data

The crop yield dataset includes crop and climate data of different states of India taken from www.kaggle.com [36]. Dataset includes 19,689 unique samples/records. The dataset covers all states in India. The prediction based on the dataset can be used for improvement in the current agriculture system.

B. Data Preprocessing

In this part of the model, stateless preprocessing operations like removal of irrelevant columns and duplicate values, exploring dataset, separating the target variable from the others, etc., are done in this phase.

C. Train-Test Split

In the proposed model, two-way splitting is performed, splitting the data into training data and Test data. The model is fed the Train data in order to identify patterns and establish its own internal rules. The Test data serves as a last check to verify if the model can accurately predict data that it has never seen. In ML, to evaluate model performance, a Train-Test split is utilized. This split also avoids overfitting and helps in real-world simulation.

D. One-Hot Encoding and Normalization

A data preprocessing method called "One-Hot Encoding" is employed to convert categorical data into a numerical representation that is understandable by ML algorithms. For every category, it generates distinct binary columns, where 0 denotes the absence of a category, and 1 denotes its existence. The next step is to convert the encoded data into a form that is required by the data mining algorithms and improves the model. This conversion or transformation is known as data normalization. Here, Z-score normalization is used for data normalization [Eq. (1)].

$$Z = \frac{X-\mu}{\sigma} \tag{1}$$

where, X represents the actual value, μ represents the population's mean, and σ is the population's deviation. A correlation heat map is used for initial feature selection.

E. RF-Based Feature Selection

Feature selection is a process to select features that are most important for the model. By lowering overfitting, increasing accuracy, and cutting down on calculation time, it may improve the performance of the model. Feature selection, which involves figuring out those features which are most relevant for building a predictive model, is a crucial step in the machine learning process.

We conducted an ablation study by performing features selection using PSO, WOA, GWO, HHO, BACO (Binary Ant Colony Optimization) and RF. But PSO, WOA, HHO, GWO, and BACO selected features that excluded the main feature; no climate features were selected by these algorithms. Therefore, we used RF feature selection for the same, as it selected climate features, which justifies this manuscript.

F. Crop Yield Prediction

Crop Yield Prediction is performed using the features selected by RF through eight models: four baseline models DT, SVR, MLR, RF, and four optimized RF models, which are optimized using PSO, GWO, HHO, and WOA optimization algorithms. The following part of this section briefly explains these models. Training dataset with N samples and p features is expressible as:

$$Dataset = \{(X_i, Y_i)\}_{i=1}^{N} \tag{2}$$

where, $X_i = (X_{i1}, X_{i2}, \dots, X_{ik})$ i.e. ith sample of the $Dataset$, Y_i is the original yield of ith sample, N is the total count of samples, $k = 1,2, \dots, p$ is a feature's index.

G. Decision Tree (DT)

A supervised learning-based approach used in ML, data mining, and statistics is decision tree learning. The DT approach can be used for classification as well as for regression. Here, it is used for regression purposes. DT approach creates a hierarchical tree structure that includes a single base node, branches, internal nodes, and leaf nodes. It functions similarly to a flowchart for step-by-step decision making [25] [26]. Fig. 2 depicts the Decision Tree Regression Approach briefly.

In DT, firstly, the mean of the node is computed as:

$$\bar{Y} = \frac{1}{n}\sum_{i=1}^{n} Y_i \tag{3}$$

where, $\bar{Y}$ represents the mean crop yield of the node, n represents total samples' count in the node, and Y_i is the actual crop yield of the ith sample in that node. After it Mean Squared Error is computed as:

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(Y_i - \bar{Y})^2 \tag{4}$$

The next step is to split, every feature is tested for different threshold values, and the weighted MSE is computed as:

$$MSE_{split} = \frac{|S_{Left}|}{|S|} MSE_{Left} + \frac{|S_{Right}|}{|S|} MSE_{Right} \tag{5}$$

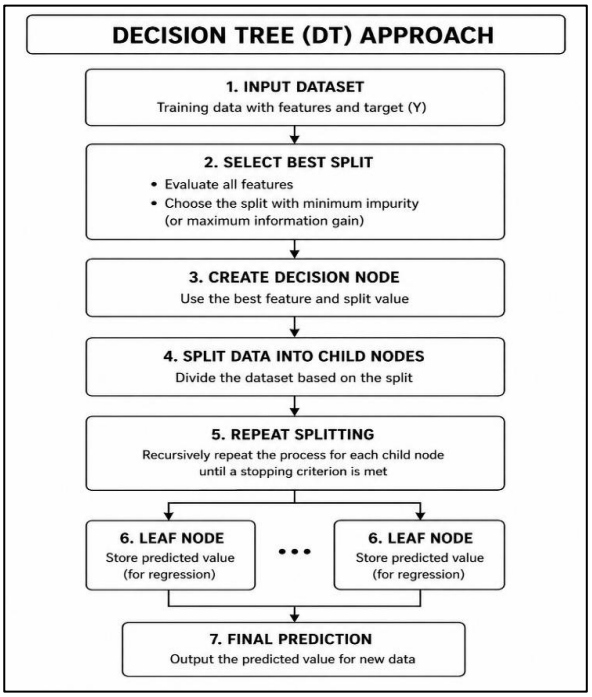

Fig. 2. Decision Tree (DT) working.

where, S is count of samples before splitting, S_{Left} is the count of samples in the left split, S_{Right} is count of samples in the right split, MSE_{Left} is the left split's Mean Square error, and MSE_{Right} is the right split's Mean Squared Error. MSE_{Left} *and* MSE_{Right} can be computed as:

$$MSE_{Left} = \frac{1}{S_{Left}} \sum \left(Y_{i\_Left} - \bar{Y}_{Left}\right) \quad (6)$$

$$MSE_{Right} = \frac{1}{S_{Right}} \sum \left(Y_{i\_Right} - \bar{Y}_{Right}\right) \quad (7)$$

where, Y_{i_Left} is the actual crop yield of a sample in the left node and Y_{i_Right} is the actual crop yield of a sample in the right node, $\bar{Y}_{Left}$ is mean crop yield of the left node, $\bar{Y}_{Right}$ is mean of crop yield of the right node. The best split is selected as:

$$(k^*, t^*) = arg\ arg\ MSE_{split}\ (k, t) \quad (8)$$

where, k is candidate's feature index, t is the candidate's threshold value, k^* is the best feature which is selected for split, t^* is the best feature's threshold, $MSE_{split}(k, t)$ is weighted MSE computed using j feature and t threshold value. Splitting is done till we reach a leaf node. Once a new sample reaches a leaf node, compute prediction as:

$$\hat{Y} = \frac{1}{n} \sum_{i=1}^{n} Y_i \quad (9)$$

where, $\hat{Y}$ is the predicted crop yield of the node, n represents total samples' count in the leaf node, Y_i actual crop yield of each sample in the leaf.

The reduction of the Mean Squared Error (MSE) is the primary goal of DT:

$$MSE = \frac{1}{N} \sum_{i=1}^{N} \left(Y_i - \hat{Y}_i\right)^2 \quad (10)$$

where, N is the training sample count, Y_i is actual crop yield of ith sample, $\hat{Y}_i$ is the predicted crop yield of the ith sample, $\left(Y_i - \hat{Y}_i\right)^2$ is the residual error squared.

H. Multiple Linear Regression (MLR)

MLR Targets Defining a Linear Relationship between a Dependent Variable and Numerous Independent Variables. Researchers Can Investigate the Effect of Multiple Independent Variables on the response simultaneously by Using Multiple Regression [27]. Fig. 3 depicts the working of the MLR Model.

MLR equation for crop yield of a sample is as follows:

$$Y_i = f(X_{i1}, X_{i2}, \ldots, X_{ik}) \quad (11)$$

Eq. (11) can be converted to the following form:

$$Y_i = \beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \cdots + \beta_k X_{ik} + \epsilon_i \quad (12)$$

where, β_0 is the intercept, $\beta_1, \beta_2, \ldots, \beta_k$ are the coefficients of features $(X_1, X_2, \ldots, X_k)$ and ϵ_i represents the random error term of ith sample $i = 1, 2, \ldots, N$.

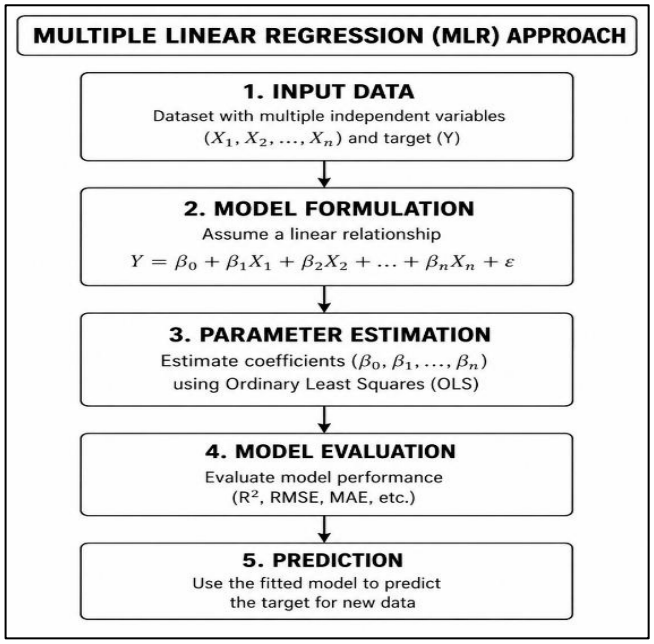

Fig. 3. Multiple Linear Regression (MLR) working.

The complete matrix representation of the above Eq. (12) can be written as:

$$\begin{bmatrix} Y_1 \\ Y_2 \\ \vdots \\ Y_n \end{bmatrix} = \begin{bmatrix} 1 & X_{11} & \cdots & X_{1k} \\ 1 & X_{21} & \cdots & X_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & X_{n1} & \cdots & X_{nk} \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_k \end{bmatrix} + \begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \vdots \\ \epsilon_n \end{bmatrix} \quad (13)$$

Ordinary Least Squares (OLS) solution is used to compute the regression coefficients as:

$$\hat{\beta} = (X^T X)^{-1} X^T Y \quad (14)$$

MLR equation for crop yield prediction of a sample is as follows:

$$\hat{Y}_i = \hat{\beta}_0 + \hat{\beta}_1 X_{i1} + \hat{\beta}_2 X_{i2} + \cdots + \hat{\beta}_n X_{ik} \quad (15)$$

Residual error (e) is computed as:

$$e = Y_i - \hat{Y}_i \quad (16)$$

The reduction of the Mean Squared Error (MSE) is the primary goal of MLR also [same as of DT, Eq. (10)].

I. Support Vector Regression (SVR)

In 1996, Vladimir N. Vapnik, Harris Drucker, Christopher J. C. Burges, Linda Kaufman, and Alexander J. Smola introduced a regression using SVM. We refer to this technique as support vector regression (SVR). SVR aims at finding the optimal fit that precisely predicts the objective variable while lowering complexity to prevent overfitting. This is accomplished by defining an ε-insensitive tube around the hyperplane that allows for a certain amount of variance between the actual and anticipated target values. A machine learning method called non-linear Support Vector Regression (SVR) is used to forecast continuous values in situations where data associations are complicated or curved [28]. Fig. 4 represents the working of the SVR approach.

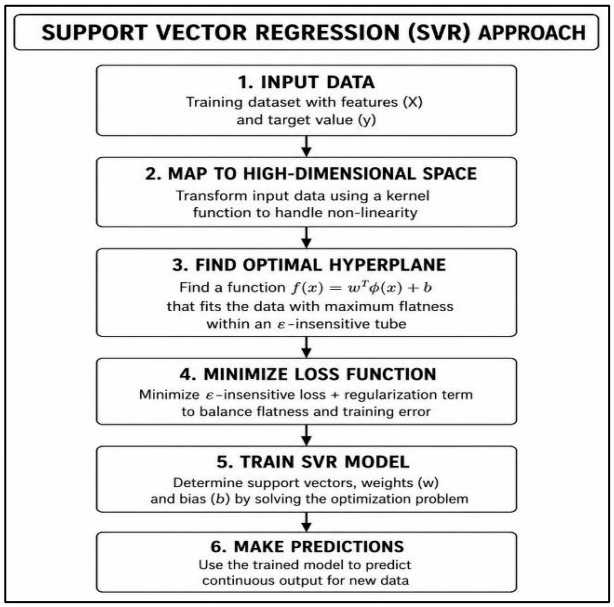

Fig. 4. Support Vector Regression (SVR) working.

The SVR non-linear function for prediction:

$$f(X) = \hat{Y} = W^T\phi(X) + \gamma \quad (17)$$

Where W^T represents the transpose of weight vector W, $\phi(X)$ is nonlinear mapping to a higher-dimensional feature space, γ is the bias.

SVR ignores small errors, known as error-insensitive, which can be written as:

$$L_\epsilon\big(Y, f(X)\big) = \begin{cases} 0 & |Y - f(X)| \le \epsilon \\ |Y - f(X)| - \epsilon & |Y - f(X)| > \epsilon \end{cases} \quad (18)$$

Where, ϵ is the width of the error-insensitive tube. SVR objective is to optimize (minimize):

$$min\,\frac{1}{2}\|W\|^2 + C\sum_{i=1}^{N}(\xi_i + \xi_i^*) \quad (19)$$

with the following conditions:

$$Y - W^T\phi(X_i) - b \le \epsilon + \xi_i \quad (20)$$

$$W^T\phi(X_i) + b - Y_i \le \epsilon + \xi_i^* \quad (21)$$

$$\xi_i, \xi_i^* \ge 0 \quad (22)$$

Where, $\|W\|^2$ is Euclidean norm of W, C is the regularization parameter, ξ_i is error above the boundary, and ξ_i^* is error below the boundary.

Eq. (19) can be converted to a dual optimization problem using Lagrange multipliers as:

$$max\,-\frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N}(\alpha_i - \alpha_i^*)(\alpha_j - \alpha_j^*)K(X_i, X_j) - \epsilon\sum_{i=1}^{N}(\alpha_i + \alpha_i^*) + \sum_{i=1}^{N}Y_i(\alpha_j - \alpha_j^*) \quad (23)$$

with conditions:

$$0 \le \alpha_i, \alpha_i^* \le C \quad (24)$$

$$\sum_{i=1}^{N}(\alpha_i - \alpha_i^*) = 0 \quad (25)$$

where, i is first sample index, j is the second sample index, α_i is Lagrange multiplier which is associated with upper error-insensitive constraint for ith sample, α_i^* is Lagrange multiplier which is associated with the lower error-insensitive constraint for ith sample, $K(X_i, X_j)$ is the function of kernel that measures the similarity between the ith and jth samples in the transformed feature space, X_i is ith training sample, X_j is jth training sample, ϵ defines the width of the insensitive tube, Y_i is the target value, C is the regularization parameter.

Kernel function used in equation is expressed as:

$$K\big(X_i, X_j\big) = exp\left(-\Upsilon\sum_{k=1}^{p}\big(x_{ik} - x_{jk}\big)^2\right) \quad (26)$$

The final prediction equation of SVR is as follows:

$$f(X) = \sum_{i=1}^{N}(\alpha_i - \alpha_i^*)exp(-\Upsilon\|X_i - X\|^2) + b \quad (27)$$

J. Random Forest (RF) Regression

RF approach is an ensemble learning approach that creates numerous decision trees and uses bagging to mix their outputs to prevent overfitting and improve prediction accuracy. Bagging and boosting ensemble learning are the two primary categories of ensemble learning techniques. In bagging ensemble learning, distinct sub-datasets are generated from the primary dataset and sent to various machine learning models. The final output or outputs are created by combining the findings of these simultaneous models. In boosting, several machine learning models use the same dataset. These models operate in a sequential manner. The first model's findings are improved by the second model, the second model's findings are improved by the third model, and so on. Bagging is the foundation of the RF method. The Random Forest automatic machine learning technique was developed in 2001 by Leo Breiman and Adèle Cutler. [29]. Fig. 5. depicts working of the RF model.

In RF regression, Multiple trees T are used in RF approach, and for each tree, a separate Dataset D_t is created. Creating of different datasets is called bootstrap sampling and can be written as:

$$D_t \subseteq D, for\ t = 1,2, \dots, T \quad (28)$$

where, D_t is bootstrap dataset for the t[th] tree, and T stands for total count of trees.

Each tree predicts the output i.e., crop yield independently as:

$$\hat{Y}_t = f_t(X) \quad (29)$$

where, $\hat{Y}_t$ is the prediction of t[th] tree, X is input feature vector.

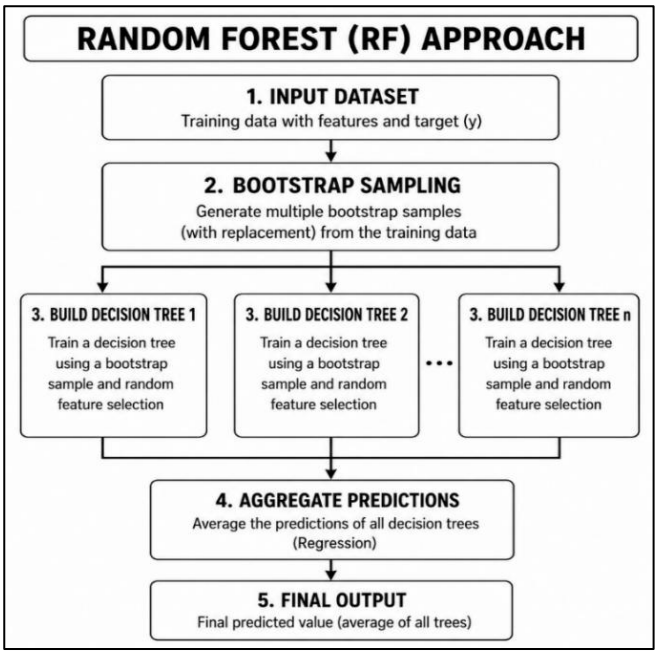

Fig. 5. Random Forest (RF) working.

The final RF Prediction equation can be written as:

$$\hat{Y} = \frac{1}{T}\sum_{i=1}^{T} f_t(X) \quad (30)$$

where, $\hat{Y}$ final predicted crop yield, T stands for the count of trees, $f_t(X)$ is predicted value of the t[th] tree.

K. Optimized RF Models

Here, four nature-inspired optimization approaches are used to optimize the RF model: PSO, GWO, HHO, and WOA algorithms. These optimization algorithms find the best parameters for the RF model.

Let d be the number of parameters of RF model to be optimized; then initialize the Lower Bound (LowB) and Upper Bound (UpB) vectors to specify the lower and upper limits of each RF parameter that is to be optimized as:

$$LowB = [LowB_1, LowB_2, \dots LowB_d] \quad (31)$$

$$UpB = [UpB_1, UpB_2, \dots UpB_d] \quad (32)$$

Initialization of position matrix X is as follows:

$$X = \begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_n \end{bmatrix} = \begin{bmatrix} X_{11} & \cdots & X_{1d} \\ X & \cdots & X_{2d} \\ \vdots & \ddots & \vdots \\ X_{n1} & \cdots & X_{nd} \end{bmatrix} \quad (33)$$

where, count of rows= n represents no. of swarms (in PSO)/ wolves (in GWO)/ hawks (in HHO)/ whales (in WOA), count of columns= d represents parameters of the RF model to be optimized. A single row represents a single particle (in PSO)/ wolf (in GWO)/ hawk (in HHO)/ whale (in WOA) as $X_i = [X_{i1}, X_{i2}, \dots, X_{id}]$. Initialization of every value in the above matrix is done as follows:

$$X_{ij} = LowB_j + r_{ij}(UpB_j - LowB_j) \quad (34)$$

where, X_{ij} is the single value of the matrix shown in equation, UpB_j is the Upper Bound value of parameter j, $LowB_j$ is the Lower Bound value of parameter j, r_{ij} is a random variable such that $0 \leq r_{ij} \leq 1$.

Eq. (31), (32), (33), and (34) are common in all four algorithms and belongs to the initialization part of it.

These four optimized RF models compute the fitness of a single row as:

$$Fitness(X_i) = RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(Y_i - \bar{Y}_i)^2} \quad (35)$$

L. PSO Optimized RF

PSO was first identified in 1995 by Kennedy and Eberhart. PSO technique is used to optimize continuous nonlinear functions. PSO is a stochastic population-based optimization method inspired by natural swarm intelligence. Every particle travels across the search space and represents a possible solution. Both individual experience and collective swarm knowledge direct movement. The approach uses a fitness function to iteratively improve solutions [30][31]. Fig. 6 represents the working of PSO-based RF optimization.

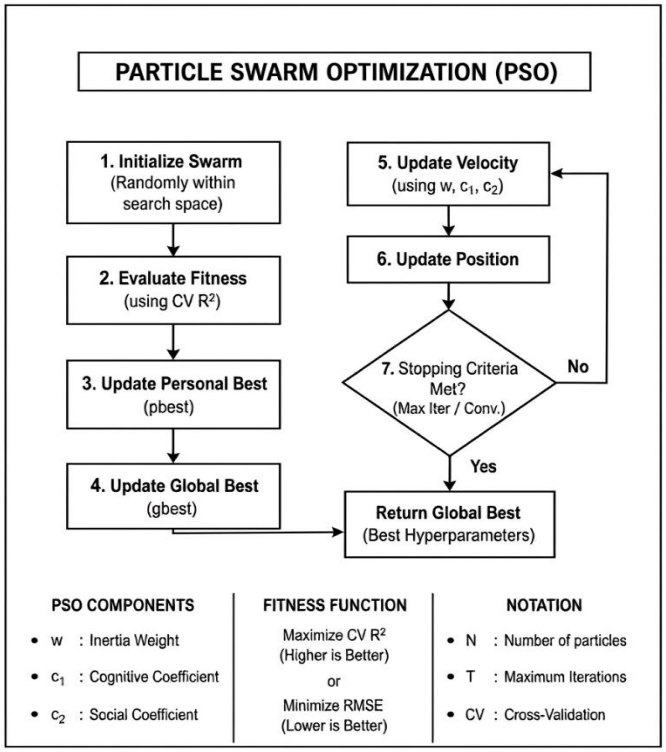

Fig. 6. Particle Swarm Optimization (PSO) working.

Steps to optimize RF model using PSO:

Initialization:

Initialize Lower Bound (LowB) and Upper Bound (UpB) vector: using Eq. (31) and (32)

Initialization of the swarm position matrix: using Eq. (33) and assign values to it using Eq. (34)

Initialize the velocity matrix

$$V = \begin{bmatrix} V_1 \\ V_2 \\ \vdots \\ V_n \end{bmatrix} = \begin{bmatrix} V_{11} \cdots V_{1d} \\ V_{21} \cdots V_{2d} \\ \vdots \quad \ddots \quad \vdots \\ V_{n1} \cdots V_{nd} \end{bmatrix} \quad (36)$$

Compute Fitness of every particle using Eq. (35)

Personal best is updated as:

$$PB_i = \begin{cases} X_{i,} & if\ Fitness(X_i) > Fitness(PB_i) \\ PB_{i,} & otherwise \end{cases} \quad (37)$$

where, PB_i best solution found by particle i

Global best's update as:

$$GB = \arg\max_i x\, Fitness(P_i) \quad (38)$$

where, GB is the best solution found by entire swarm.

Update Velocity and particle position:

Velocity update:

$$V_i^{t+1} = \omega V_i^t + c_1 r_1 (PB_i - X_i^t) + c_2 r_2 (GB - X_i^t) \quad (39)$$

where, ω represents inertia weight, c_1 is cognitive coefficient, c_2 is the social coefficient, t represents current iteration.

Particle position update:

$$X_i^{t+1} = X_i^t + V_i^{t+1} \quad (40)$$

Repeat steps 2 to 5 until convergence is attained or the maximum number of iterations is attained.

RF is optimized with the best solution as,

$$X_{best} = GB \quad (41)$$

M. GWO Optimized RF

A nature-inspired metaheuristic algorithm called Grey Wolf Optimization (GWO) that imitates the leadership organization and hunting techniques of grey wolves in the wild. Seyedali Mirjalili first presented it in 2014. The best fit, according to GWO, is the Alpha wolf (α); the second best fit is the Beta wolf (β),the third best fit is the Delta wolf (δ); and the Omega wolves (ω) are the remaining possible options [32][33]. Fig. 7 depicts the working of GWO Based RF optimization.

Steps to optimize the RF model using GWO:

Initialization:

Initialize Lower Bound (LowB) and Upper Bound (UpB) vector: using Eq. (31) and (32)

Initialization of the wolf position matrix: using Eq. (33) and assign values to it using Eq. (34)

Compute Fitness for every wolf using Eq. (35)

Identify the Alpha (α), the Beta (β), the Delta (δ) and Omega (ω) wolves as:

$$X_\alpha = X_i\ with\ best\ Fitness(X_i) value \quad (42)$$

$$X_\beta = X_i\ \ with\ second\ best\ Fitness(X_i) value \quad (43)$$

$$X_\delta = X_i\ with\ third\ best\ Fitness(X_i) value \quad (44)$$

$$X_\omega = X_i\ with\ rest\ of\ the\ wolves \quad (45)$$

Compute parameter a as:

$$a = 2 - \frac{2t}{T} \quad (46)$$

where, t shows the current iteration, and T stands for maximum iteration. Now compute the coefficient as:

$$A = 2_{ar_1} - a \quad (47)$$

$$C = 2r_2 \quad (48)$$

where, A and C are coefficients, where r_1 and r_2 are random values such that $0 \le r1, r2 \le 1$

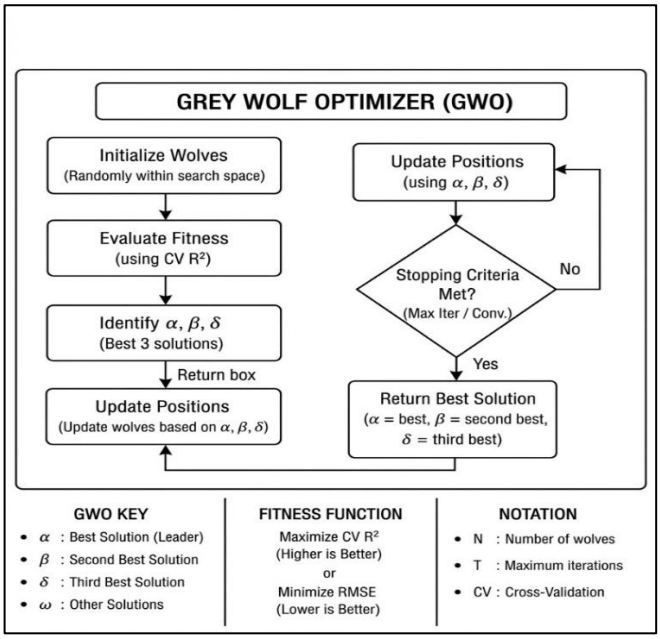

Fig. 7. Grey Wolf Optimization (GWO) working.

Compute the distance from X_α, X_β, and X_δ wolves and Compute candidate positions based on D_α, D_β, and D_δ as:

Distance from X_α, X_β, and X_δ wolves as:

$$Distance_\alpha = |C_1 X_\alpha - X| \quad (49)$$

$$Distance_\beta = |C_1 X_\beta - X| \quad (50)$$

$$Distance_\delta = |C_1 X_\delta - X| \quad (51)$$

Candidate positions based on D_α, D_β, and D_δ as:

$$X_1 = X_\alpha - A_1 Distance_\alpha \quad (52)$$

$$X_2 = X_\beta - A_2 Distance_\beta \quad (53)$$

$$X_3 = X_\delta - A_3 Distance_\delta \quad (54)$$

Update Wolf Position as:

$$X_{t+1} = \frac{X_1 + X_2 + X_3}{3} \quad (55)$$

Eq. (55) will update every wolf except Alpha wolf.

Check the updated position for its upper bounds and lower bounds as

$$min(UpB, max(LowB, X)) \quad (56)$$

Evaluate Fitness again and Update X_α, X_β, and X_δ again

Until the maximum count of iterations is attained, repeat steps 2 through 7.

RF is optimized with best solution as:

$$X_{best} = X_\alpha \quad (57)$$

N. HHO Optimized RF

Ali Asghar Heidari and associates introduced the well-known population-based, nature-inspired HHO metaheuristic algorithm in 2019. It imitates Harris's hawks' coordinated foraging and "surprise pounce" hunting techniques. Exploration, escaping energy shifts, and exploitation tactics are important elements of the HHO optimizer [34]. Fig. 8 represents the working of HHO-based RF optimization.

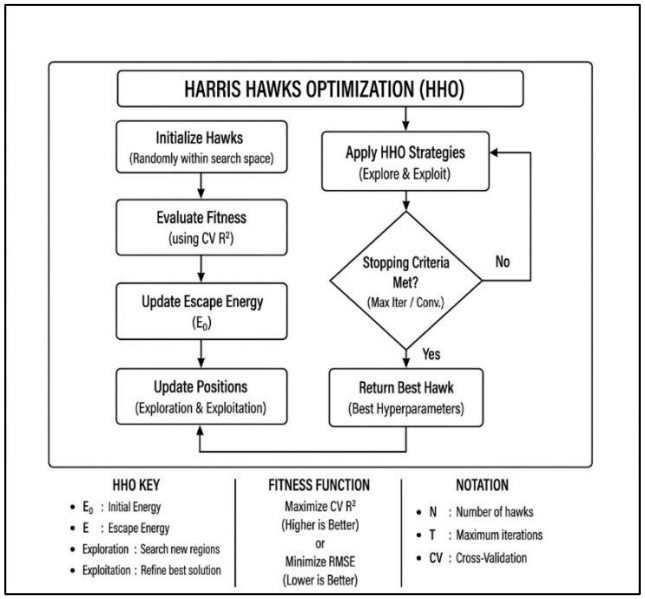

Fig. 8. Harris Hawks Optimization (HHO) working.

Steps to optimize RF model using HHO:

Initialization:

Initialize Lower Bound (LowB) and Upper Bound (UpB) vector: using Eq. (31) and (32)

Initialization of Hawks position matrix: using Eq. (33) and assign values to it using Eq. (34)

Compute Fitness for every hawk using Eq. (35)

Identify the best hawk (Rabbit) as:

$$X_{rabbit} = \arg\max_i Fitness(X_i) \quad (58)$$

Calculate the escaping energy that regulates the change from exploration to exploitation using the equation below:

$$E_0 = 2r - 1 \quad (59)$$

where, r is a random value such that $0 \le r \le 1$, current escaping energy is expressed as:

$$E = 2E_0\left(1 - \frac{t}{T}\right) \quad (60)$$

where, t shows the current iteration and T stands for the maximum number of iterations

Exploration phase: When $|E| \ge 1$, the hawk explores the search space as:

$$X(t+1) = X_{random}(t) - r1|X_{random}(t) - 2r_2X(t)| \quad (61)$$

where, X_{random} is a randomly selected hawk.

Explotation phase: When $|E| < 1$, hawk exploits the best solution (Rabbit) as :

$$X(t+1) = X_{rabbit} - E|JX_{rabbit} - X(t)| \quad (62)$$

where, $J = 2(1 - r)$, and r is a random such that $0 \le r \le 1$

Checking new computed value for boundaries using UB and LB as

$$X = min(UpB, max(LowB.X) \quad (63)$$

Evaluate Fitness again

Update the Rabbit again

Until the maximum number of iterations is attained, repeat steps 2 through 9.

RF is optimized with best solution as

$$X_{best} = X_{rabbit} \quad (64)$$

O. WOA Optimized RF

Seyedali Mirjalili and Andrew Lewis introduced the Whale Optimization method (WOA), a metaheuristic optimization method inspired by nature, in 2016. Only humpback whales exhibit the unusual behavior known as "bubble-net feeding." The whale optimization algorithm (WOA) provides a theoretical description of the spiral bubble-net feeding maneuver. WOA mimics hunting behavior by pursuing the prey with a random or optimum search agent. WOA simulates humpback whale bubble-net attacks using a spiral [35]. Fig. 9 depicts WOA-based RF optimization working.

Steps to optimize RF model using WOA:

Initialization:

Initialize Lower Bound (LowB) and Upper Bound (UpB) vector: using Eq. (31) and (32)

Initialization of Whale position matrix: using Eq. (33) and assign values to it using Eq. (34)

Compute Fitness for every whale using Eq. (35)

Identify best whale as:

$$X^* = \arg\max_i Fitness(X_i) \quad (65)$$

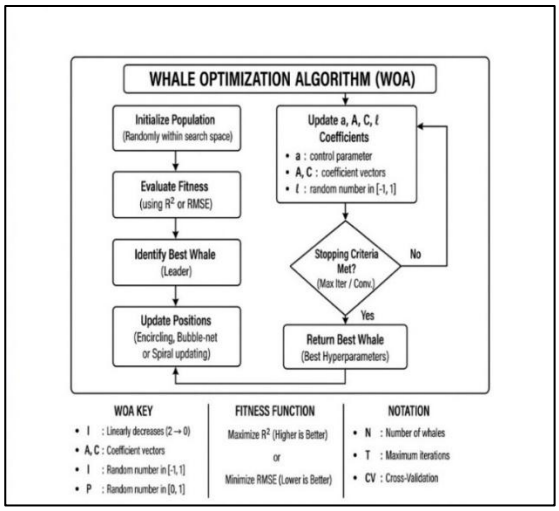

Fig. 9. Whale Optimization Algorithm (WOA) working.

Update control parameter as:

$$a = 2 - \frac{2t}{T} \quad (66)$$

where, t shows the current iteration and T stands for the maximum number of iterations

Compute Coefficient Vectors as:

$$A = 2_{ar_1} - a \quad (67)$$

$$C = 2r_2 \quad (68)$$

where, A and C are coefficients, where r_1 and r_2 are random values such that $0 \leq r1, r2 \leq 1$

Choose the search strategy based on a randomly generated p value between 0 and 1 as follows:

Case 1: If $p < 0.5$ and $|A| < 1$, compute distance to whale and update position as:

$$Distance = |CX^* - X| \quad (69)$$

$$X(t+1) = X^* - ADistance \quad (70)$$

Case 2: If $p < 0.5$ and $|A| \geq 1$, compute distance to whale and update position as:

$$D = |CX_{random} - X| \quad (71)$$

$$X(t+1) = X_{rand} - ADistance \quad (72)$$

Case 3: If ≥ 0.5 , compute distance to whale and update position as:

$$Distance' = |X^* - X| \quad (73)$$

$$X(t+1) = Distance' e^{bl} \cos(2\pi l) + X^* \quad (74)$$

where, b is the spiral constant, generally taken as 1, l ranges $-1 \geq l \geq 1$

Checking new computed value for boundaries using J and LB as

$$X = min(UpB, max(LowB.X)) \quad (75)$$

Evaluate Fitness again

Update the best whale as:

$$X^* = X_i \quad (76)$$

Repeat steps 2 to 9 until the maximum number of iterations are reached.

RF is optimized with best solution as

$$X_{best} = X^* \quad (77)$$

IV. Evaluation Metrics

The performance of the proposed crop yield prediction framework is examined using R Squared, Mean Absolute Error, Root Mean Square Error, and 5-Fold CV Score.

A. Mean Absolute Error (MAE)

The average absolute difference between actual and predicted data is measured as mean absolute error. It provides results in the target variable's unit. It can be evaluated as:

$$MAE = \frac{1}{N}\sum_{i=1}^{N}\left|Y_i - \hat{Y}_i\right| \quad (78)$$

where, N count of observations is, Y_i is the actual value, $\hat{Y}_i$ is the predicted value.

B. Root Mean Square Error (RMSE)

The square root of Mean Squared Error (MSE) is called Root Mean Squared Error. It improves interpretability by returning the result to the target variable's original unit while maintaining the severe penalty for significant errors. It is evaluated as:

$$RMSE = \sqrt{MSE} \quad (79)$$

$$\text{where, } MSE = \frac{1}{N}\sum_{i=1}^{N}(Y_i - \bar{Y}_i)^2 \quad (80)$$

C. R Squared (R^2)

It is also known as the Coefficient of Determination. R-squared indicates how much of the variance in the target variable can be explained by the regression model. It is judged as:

$$R^2 = 1 - \frac{\sum_{i=1}^{N}(Y_i - \hat{Y}_i)^2}{\sum_{i=1}^{N}(Y_i - \bar{Y}_i)^2} \quad (81)$$

D. Cross-Validation Score (CV)

$$R_k^2 = 1 - \frac{\sum_{i=1}^{Nk}(Y_i - \hat{Y}_i)^2}{\sum_{i=1}^{Nk}(Y_i - \bar{Y}_i)^2} \quad (82)$$

$$CV_{Score} = \frac{1}{k}\sum_{k=1}^{5} R_k^2 \quad (83)$$

5-fold CV Score is used in the proposed model as:

$$CV_{Score} = \frac{R_1^2 + R_2^2 + R_3^2 + R_4^2 + R_5^2}{5} \quad (84)$$

V. Results and Discussion

All four of the optimized models are found to have outperformed the baseline models. RF Parameters' bounds and best optimized parameters using the PSO optimizer are shown in the following table (Table I):

TABLE I. RF Parameters' Bounds and Best Optimized Parameters

RF Parameter	Lower Bound (LB)	Upper Bound (UB)	Final Optimized Value (PSO-RF)
n_estimators	50	500	126
max_depth	5	30	27
min_samples_split	2	20	2
min_samples_leaf	1	10	1
max_features	0.3	1.0	0.951048340383684

RF Optimization resolves black box Interpretation gap: In our model, RF feature selection is used, which prevents dropping domain-critical climate features. RF Optimization resolves the static hyperparameter gap: Our framework addresses this gap by optimizing the RF model using PSO, GWO, WOA, and HHO optimizers, which optimize the RF model based on predefined Lower and Upper Bounds of the RF model's parameters.

PSO-optimized RF performed the best with R^2 Value= 98.32. Fig. 10 represents the comparison of models based on R^2value.

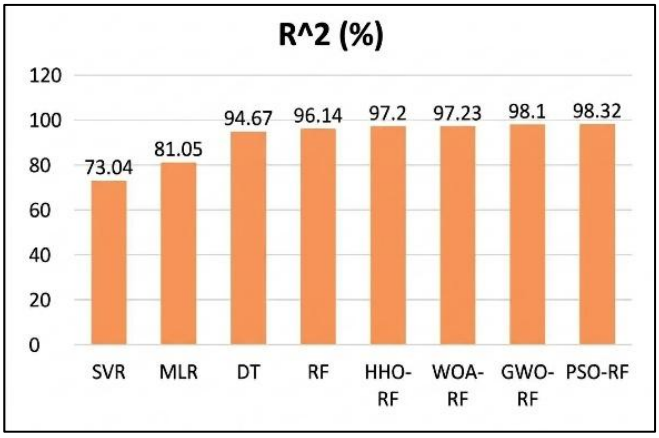

Fig. 10. Comparison of models based on R^2 value.

All four of the optimized models are found to have outperformed the baseline models. And PSO Optimized RF performed the best with CV_Score =97.22. Fig. 11 represents the comparison of models based on the CV_Score value.

All four of the optimized models are found to have outperformed the baseline models. And PSO Optimized RF performed the best with MAE =9.2766. Fig. 12 represents the comparison of models based on MAE value.

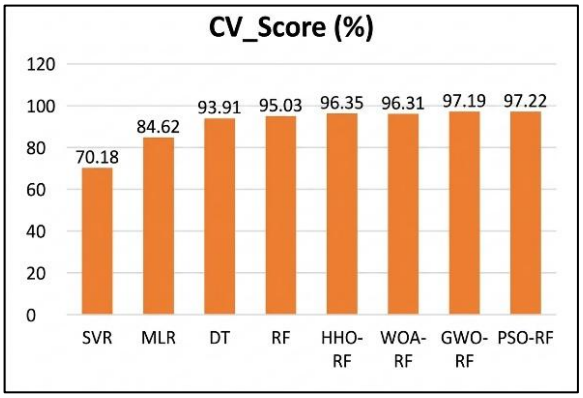

Fig. 11. Comparison of models based on CV_Score value.

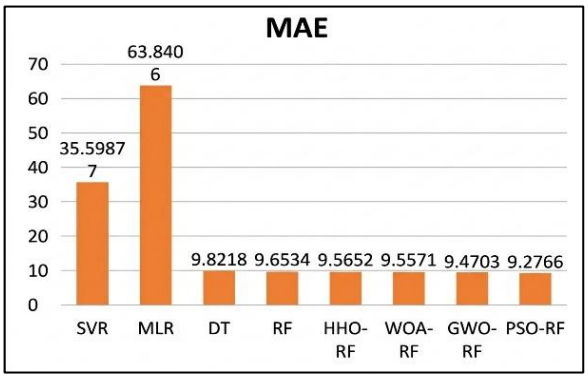

Fig. 12. Comparison of models based on MAE value.

It is observed that RMSE value is quite large. It is due to the dataset, as it contains many samples with 0 or extremely low crop yield. We cannot delete these samples, as it shows that during that period crop yield was very low or the crop was completely wasted, and we want to maintain the originality of the dataset. These yield may be low due to lack of water or weather condition or may be due to pest in the crop or due to weed or due to disaster or may be some other reason. Our algorithms focus on the other samples and predicted low or 0 crop yield values with high error. These samples are few; that is why RMSE and MSE are highly impacted, but have very little impact on R^2. All four of the optimized models are found to have outperformed the baseline models. And PSO-optimized RF performed the best with RMSE value = 116.1088. Fig. 13 represents the comparison of models based on RMSE value.

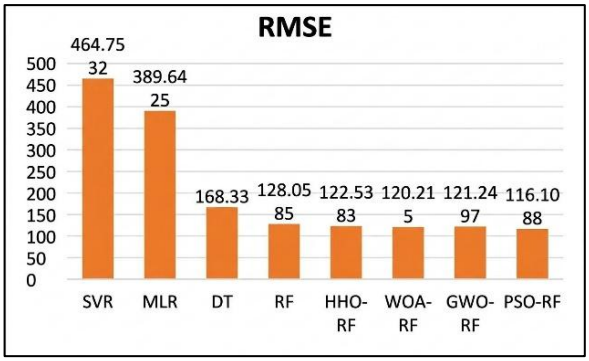

Fig. 13. Comparison of models based on RMSE value.

A. Comparison of Optimized RF Models with Base Models

Tabular comparison of baseline models and Optimized RF models is shown in Table II.

TABLE II. COMPARISON USING PERFORMANCE METRICS

Model	R^2 %	CV_Score (%)	MAE	RMSE
SVR	73.04	70.18	35.5987	464.7532
MLR	81.05	84.62	63.8406	389.6425
DT Regression	94.67	93.91	9.8218	168.3300
RF Regression	96.14	95.03	9.6534	128.0585
HHO-RF	97.20	96.35	9.5652	122.5383
WOA-RF	97.23	96.31	9.5571	120.2150
GWO-RF	98.10	97.19	9.4703	121.2497
PSO-RF	98.32	97.22	9.2766	116.1088

VI. CONCLUSION AND FUTURE SCOPE

In this research work, a data analytic framework for crop yield prediction is proposed with a comparison between four baseline models and four optimized RF models. The framework is based on the impact of climate change. The proposed framework mainly comprises of 5 phases: Data input; Data preprocessing; Feature selection based on the RF approach; Train and Test split; After the split all four baseline models are trained and perform crop yield prediction with the computation of four performance metrics: R^2, MAE, RMSE; 5 Fold CV score is computed; next, out of the four baseline models RF model is chosen as it performed best. RF model is further improved using four nature-inspired models: PSO, GWO, HHO, and WOA. It is observed that all four optimized RF models performed better than the four baseline models. And out of four optimized RF models, PSO optimized performed the best. Therefore, the RF-PSO hybrid model is proposed. The proposed framework's R^2 (%) value=98.32, MAE value= 9.2766, CV score (%) =97.22, RMSE=116.1088. High RMSE is due to samples with 0 crop yield or very low crop yield. Thus, the proposed framework is suitable for crop yield detection using RF optimization with the PSO optimization technique. In the future, the latest modern metaheuristics can be applied for further improvement in the model.

Student-Disjoint Cross-Module Benchmarking for Calibrated Early Warning in Online Learning

Mika Lim
University Innovation Center, Seoul National University, Seoul, Republic of Korea

***Abstract*—Early-warning models in online learning are commonly evaluated with random data partitions, even though deployment often requires transfer to a course that supplied no training data. This study establishes a leakage-resistant benchmark for cross-module risk prediction using the Open University Learning Analytics Dataset. The analysis covered 32,593 enrollments from 28,785 learners, seven modules, 22 module presentations, and 10,655,280 daily virtual learning environment interaction records. Predictions were produced after 7, 14, and 28 days for learners still active at each cutoff. Logistic regression, random forest, and histogram gradient boosting were evaluated by leaving one entire module out and removing every learner who also appeared in the held-out module from training. Probability calibration was learned only from student-grouped out-of-fold predictions, using the same nested procedure in both validation designs. Random student-disjoint cross-validation yielded an area under the receiver operating characteristic curve (AUROC) of 0.716, whereas held-out-module evaluation yielded an AUROC of 0.661, revealing substantial contextual optimism. Under the fixed hyperparameter configurations used in this benchmark, logistic regression achieved higher cross-module performance than both nonlinear models. A virtual-learning-environment-only specification preserved discrimination while improving precision-recall performance and Brier score relative to adding assessment-submission features. Calibration nevertheless varied markedly across modules, indicating that global post-hoc calibration did not eliminate course-level distribution shift. The benchmark shows that student independence, course separation, feature availability, and probability quality must be evaluated jointly before an early-warning model is considered transferable.**

I. Introduction

Learning management systems record how learners access resources, participate in activities, and submit assessments. These traces support early-warning models that prioritize timely academic support. Research using the Open University Learning Analytics Dataset (OULAD) and other large online-learning corpora has shown that behavioral variables can predict failure or withdrawal before a course ends [1]–[4]. Transfer to a new course, however, is a different problem from predicting held-out learners sampled from the same mixture of courses. Course organization, assessment timing, resource structure, and outcome prevalence can change the relationship between a feature and the target. A model may therefore appear accurate in a random split yet fail when used in an unseen instructional context.

The distinction matters technically and educationally. Repeated learners can enroll in more than one module, allowing student-level regularities to cross a nominal train-test boundary. Random partitions also mix course contexts, so the test distribution resembles the training distribution more closely than a future deployment course. Leakage and distribution mismatch can inflate claims in machine-learning-based science [10]. Recent learning-analytics research has consequently emphasized transfer, external validity, and model stability across courses and cohorts [5]–[9]. Yet many studies still optimize discrimination alone. Early-warning systems use predicted probabilities to allocate scarce support; poor calibration can over- or under-estimate the number of learners requiring intervention even when rank discrimination is acceptable [11], [12].

A second concern is feature legitimacy. Assessment scores can be highly predictive, but OULAD reports submission dates rather than the time at which grades became available. Treating every recorded score as known at the prediction cutoff can therefore introduce timing ambiguity. Demographic variables may improve average performance while creating governance and fairness concerns. Course-specific assessment counts and due-date patterns may also transfer poorly because they encode instructional design rather than general engagement. A deployable benchmark should distinguish registration data, virtual learning environment (VLE) behavior, submission behavior, recorded scores, and protected or sensitive attributes instead of aggregating them into an undifferentiated feature set.

The computational contribution of this study is an evaluation protocol rather than a new classifier: a reproducible student-disjoint, leave-one-module-out benchmark for calibrated early-warning prediction on all seven OULAD modules. It makes four contributions. First, it separates both modules and learner identities between outer training and test sets. Second, it evaluates three prediction horizons while defining a dynamic risk set of learners who remain enrolled at each cutoff. Third, it compares feature families according to operational availability and transferability. Fourth, it evaluates probability quality, module heterogeneity, paired model differences, and model-agnostic feature importance rather than reporting a single accuracy value. The technical novelty lies in coupling these safeguards within a single transfer benchmark rather than evaluating them independently: learner identities and modules are separated at the outer boundary, the risk set is redefined at each prediction cutoff, calibration is learned entirely within training data, and feature families are compared under the same deployment-oriented protocol.

RQ1. How do validation design, prediction horizon, and model class affect cross-module discrimination and probability quality?

RQ2. Which feature families provide the most transferable balance of discrimination and calibration for an unseen module?

RQ3. How stable are calibrated risks across held-out modules, outcomes, and time, and which observed behaviors drive the predictions?

II. Related Work

A. Early Risk Prediction from Learning Traces

OULAD links demographics, registration, assessments, course structure, and daily VLE interactions for seven anonymized modules [1]. Deep and ensemble models have achieved strong within-dataset prediction, and flexible feature-selection methods can reduce manual engineering [2], [3]. Higher temporal granularity often improves early prediction [4]. These findings establish the predictive value of activity traces, but a model trained and tested within a pooled course mixture answers a narrower question than transfer to a previously unseen module. High apparent accuracy may also depend on final-course information, assessment schedules, or learners represented in both partitions.

B. Cross-Course Generalization

Transfer-learning research has trained models across multiple massive open online courses and used course metadata or prior iterations to warm-start prediction [5]. Other work shows that generalizability depends on course and cohort context and that behavioral models can lose stability after transfer [6], [13]. Recent studies have evaluated digital-trace models across computer-science courses [7] and multiple technical-education courses [8], while modelability has been proposed as a design principle for scalable predictive learning analytics [9]. The present study complements this literature by combining course-disjoint testing with complete learner-identity separation, multiple early cutoffs, feature-availability ablations, and calibration analysis on a widely reused public benchmark.

C. Calibration, Errors, and Transparency

The area under the receiver operating characteristic curve (AUROC) measures ranking, not whether a predicted risk of 0.60 corresponds to an observed event rate near 0.60. Modern classifiers can be miscalibrated even when discrimination is strong [14]. Platt scaling provides a simple post-hoc mapping from model scores to probabilities [15], while Brier score [17] and expected calibration error [14] summarize probability accuracy. Because non-success is common but not balanced uniformly across modules, area under the precision-recall curve is also necessary [16]. Educational consequences further require examination of errors and explanation: confident mistakes can erode adoption, and important contextual causes of non-success may remain absent from platform data [12]. Transparent comparisons between simple and complex models are therefore preferable to assuming that higher-capacity algorithms will generalize better [21].

III. Methods

A. Data Source and Integrity Checks

The study used OULAD, released under a Creative Commons Attribution 4.0 license [1]. The seven relational tables were joined by module, presentation, learner, assessment, and VLE-site identifiers. Before modeling, record counts and module-presentation coverage were checked against the data descriptor. The verified data contained 32,593 enrollment records, 28,785 unique learners, seven modules, 22 presentations, 206 assessments, 6,364 VLE sites, and 10,655,280 student-VLE daily interaction records. No duplicate enrollment keys or missing outcomes were present.

The binary target was non-success, defined as a final result of Fail or Withdrawn; Pass and Distinction formed the comparison class. At each prediction day, learners whose recorded unregistration date preceded the cutoff were excluded because they were no longer candidates for prospective support. This dynamic risk-set definition produced 29,196 active enrollments at day 7, 28,128 at day 14, and 27,553 at day 28. The positive prevalence declined from 0.473 to 0.442 as already-withdrawn learners left the active set. A fixed-cohort sensitivity analysis restricted all three horizons to the 27,553 enrollments still active at day 28. The active cohorts and corresponding outcome prevalence are summarized in Table I.

TABLE I. Active Cohorts and Outcome Prevalence

Day	Active n	Non-success n	Prevalence
7	29,196	13,811	0.473
14	28,128	12,743	0.453
28	27,553	12,168	0.442

B. Feature Construction

All time-varying features used records dated from course day 0 through the day preceding the cutoff, so no same-day or future event entered a prediction. Registration variables comprised registration timing, previous attempts, and studied credits. VLE features summarized total, recent, and first-week clicks; active days and their ratio to elapsed days; daily mean, standard deviation, and maximum; number of unique resources; recent-to-first-week ratio; and clicks within 14 activity categories. Nonnegative skewed counts were transformed by $\log(1+x)$. Submission-behavior features counted submitted and late assessments, indicated whether any assessment had been submitted, and summarized timing relative to due dates.

Five feature specifications were evaluated. Registration used three static variables. VLE added 23 module-agnostic activity features. Operational added four assessment-submission variables but no scores. Score-augmented added mean, minimum, and maximum recorded score as a timing-sensitivity analysis. Demographic-augmented added gender, region, prior education, deprivation band, age band, and disability to the operational set. The primary transfer interpretation emphasized the VLE and operational specifications; scores and demographics were not treated as required deployment inputs.

Preprocessing was fit only on each training set. Numeric missing values used the training median, counts used structural zeros where no event occurred, and demographic categories used the training mode plus one-hot encoding.

C. Models and Calibration

Three classifiers represented increasing functional complexity: L2-regularized logistic regression, a random forest with 160 trees and a minimum leaf size of 10 [18], and histogram gradient boosting with 180 iterations, learning rate 0.08, 31 leaf nodes, and L2 regularization. Hyperparameters were fixed across modules and cutoffs to avoid adapting the benchmark to a held-out target. Accordingly, comparisons among model classes refer to these prespecified configurations and should not be interpreted as an exhaustive test of each algorithm after hyperparameter optimization. Model-class comparisons used the operational specification at all three cutoffs. Day-28 feature-family analyses used logistic regression, the strongest cross-module model in that comparison, to isolate feature effects without multiplying the model grid. Logistic numeric inputs were standardized within the training pipeline. Implementations used scikit-learn [19] with a fixed random seed.

For each outer fold, 4-fold stratified group cross-validation generated out-of-fold predictions within the training modules, with learner identifier as the group. A Platt logistic calibrator was fit to those out-of-fold scores and then applied to the untouched held-out module [15]. The F1 threshold was selected from calibrated training predictions only. Uncalibrated and calibrated probabilities were retained; threshold-dependent results were secondary because intervention capacity was not specified.

D. Validation Design and Metrics

The principal evaluation used seven leave-one-module-out folds. In each fold, all enrollments from one module were held out. Every enrollment of a learner appearing in that test module was then removed from the remaining training modules. Depending on the fold, this identity filter removed 2 to 1,772 otherwise eligible training rows. This design estimates transfer to a new module for learners unseen during model fitting. A student-disjoint stratified 5-fold split that ignored module boundaries served as the conventional comparator. The comparator used the same 4-fold, student-grouped inner procedure for Platt calibration, ensuring that the contrast changed the module boundary rather than the calibration protocol.

Discrimination was assessed with AUROC and area under the precision-recall curve (AUPRC). Probability quality was assessed with Brier score, log loss, and expected calibration error computed with ten equal-frequency bins. Accuracy, balanced accuracy, precision, recall, and F1 were reported for training-derived thresholds. Student-cluster bootstrapping preserved repeated enrollments when calculating 95 percent intervals and paired model differences. Permutation importance was computed within each held-out module as the mean decrease in AUROC over three independent permutations of each feature. No normalization was applied to the importance values. Module-specific importance estimates were then aggregated using held-out-module sample sizes as weights. Negative permutation importance values were retained without truncation or transformation; Fig. 5 displays only the nine highest-ranked features.

IV. Results

A. Model and Horizon Comparison

Under the prespecified hyperparameter configurations, logistic regression achieved the highest pooled cross-module AUROC at every horizon. With operational features, calibrated AUROC increased from 0.654 at day 7 to 0.667 at day 14 and then decreased slightly to 0.661 at day 28 (Fig. 1 and Table II). The corresponding day-28 AUPRC, Brier score, and expected calibration error were 0.594, 0.237, and 0.071; AUPRC exceeded the active-cohort prevalence baseline of 0.442. The student-cluster bootstrap interval for day-28 AUROC was 0.655 to 0.667. Under these fixed configurations, random forest and histogram gradient boosting showed lower transfer performance than logistic regression. At day 28, logistic regression exceeded random forest by 0.0136 AUROC (95 percent interval 0.0104 to 0.0170) and histogram gradient boosting by 0.0082 (0.0050 to 0.0115). Its Brier score was lower by 0.0063 and 0.0060, respectively, with both paired intervals excluding zero.

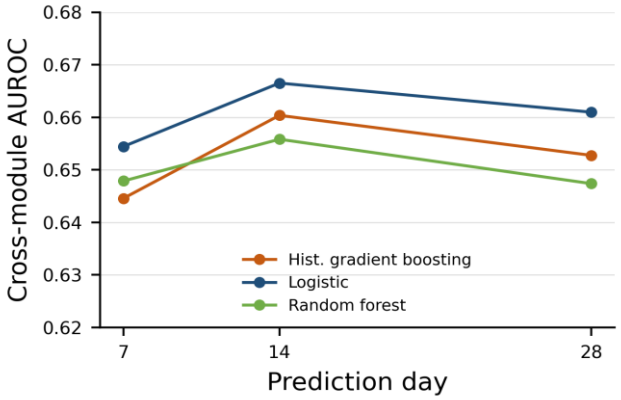

Fig. 1. Student-disjoint held-out-module AUROC by prediction day and model using operational features.

TABLE II. Cross-Module Performance with Operational Features

Day	Model	AUROC	AUPRC	Brier
7	Logistic	0.654	0.611	0.232
7	RF	0.648	0.598	0.234
7	HGB	0.645	0.600	0.234
14	Logistic	0.667	0.615	0.229
14	RF	0.656	0.596	0.231
14	HGB	0.660	0.604	0.230
28	Logistic	0.661	0.594	0.237
28	RF	0.647	0.575	0.243
28	HGB	0.653	0.574	0.243

RF: random forest; HGB: histogram gradient boosting. Values use Platt-calibrated probabilities.

B. Validation-Design Gap

With the same nested calibration protocol, the conventional student-disjoint 5-fold design, which mixed modules across

folds, produced AUROC 0.716, AUPRC 0.673, Brier score 0.211, and expected calibration error 0.017 at day 28. The stricter student-disjoint held-out-module design produced 0.661, 0.594, 0.237, and 0.071, respectively (Fig. 2). Thus, merely preventing learner overlap did not simulate deployment to an unseen module. Module separation exposed an AUROC optimism gap of 0.055 and a more than fourfold increase in calibration error. This result answers the validation component of RQ1: context mixing remained a major source of optimistic evaluation after learner identities were separated.

The magnitude of this gap should not be treated as directly equivalent to prior transfer results because the prediction targets, datasets, and validation schemes differ across studies. Kleter et al. [6] evaluated both numerical and binary predictive models across courses and cohorts and reported performance degradation after generalization, with the extent of degradation depending on initial model performance. Schwerter et al. [7] reported in-sample AUROC ranges of 0.73–0.81 for Elastic Net, 0.94–1.00 for random forest, and 0.77–0.99 for XGBoost, while cross-course and cross-institution performance declined and varied substantially across source-target pairings. By contrast, the present 0.716-to-0.661 comparison holds the dataset, outcome definition, feature specification, learner-disjoint rule, and nested calibration procedure constant, so the 0.055 difference more directly isolates the effect of enforcing module separation.

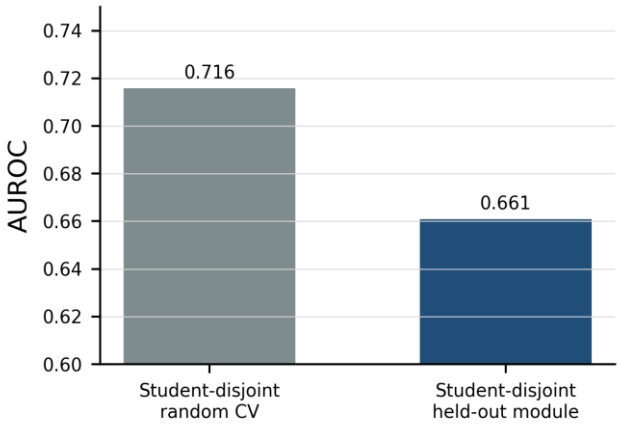

Fig. 2. Validation design changes apparent day-28 logistic performance despite student-disjoint partitions.

C. Feature Transferability

Feature-family results showed that additional information was not uniformly transferable (Table III and Fig. 3). Registration data alone provided weak discrimination. VLE features increased AUROC to 0.660 and AUPRC to 0.604 while achieving the lowest Brier score among the behavior-based models, 0.230. Adding submission behavior changed AUROC by less than 0.001 but reduced AUPRC by 0.010 and increased Brier score by 0.0068. In paired student-cluster bootstrap comparisons, the VLE-minus-operational AUROC difference was -0.0009 (95 percent interval -0.0055 to 0.0036), whereas its AUPRC advantage was 0.0102 (0.0057 to 0.0145) and its Brier difference was -0.0068 (-0.0085 to -0.0050). The latter two improvements were robust.

Recorded scores raised AUROC to 0.672 but reduced AUPRC and worsened Brier score. Demographics yielded the highest AUROC, 0.684, and AUPRC, 0.619, but used six sensitive or governance-relevant variables. These sensitivity results do not establish that such variables should be deployed. Rather, they demonstrate that feature selection changes the balance between ranking, probability quality, timing validity, and responsible use. The VLE-only specification provided the strongest transfer-oriented compromise for RQ2.

TABLE III. DAY-28 LOGISTIC FEATURE-SET ABLATION

Feature set	p	AUROC	AUPRC	Brier	ECE
Registration	3	0.551	0.507	0.243	0.015
VLE	26	0.660	0.604	0.230	0.044
Operational	30	0.661	0.594	0.237	0.071
+ Scores	33	0.672	0.574	0.238	0.084
+ Demographics	36*	0.684	0.619	0.230	0.067

p counts six demographic fields before one-hot expansion. ECE: expected calibration error.

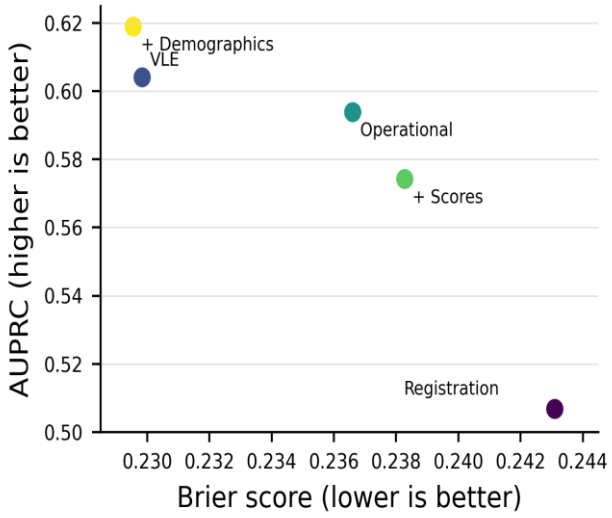

Fig. 3. Trade-off between precision-recall performance and probability accuracy across feature families.

D. Module Heterogeneity and Calibration

Held-out-module results varied substantially. For the day-28 operational logistic model, AUROC ranged from 0.635 for GGG to 0.736 for EEE. Expected calibration error ranged from 0.027 for CCC to 0.357 for GGG. The VLE-only reliability curves showed the same broader pattern: some modules lay above the identity line and others below it (Fig. 4). Global Platt scaling slightly improved pooled expected calibration error for logistic regression, from 0.073 to 0.071, but it did not correct target-specific base-rate and feature-distribution shifts. For random forest and histogram gradient boosting at day 28, Platt scaling worsened pooled Brier score and expected calibration error. Calibration therefore must be checked on each destination context rather than assumed to transfer with discrimination.

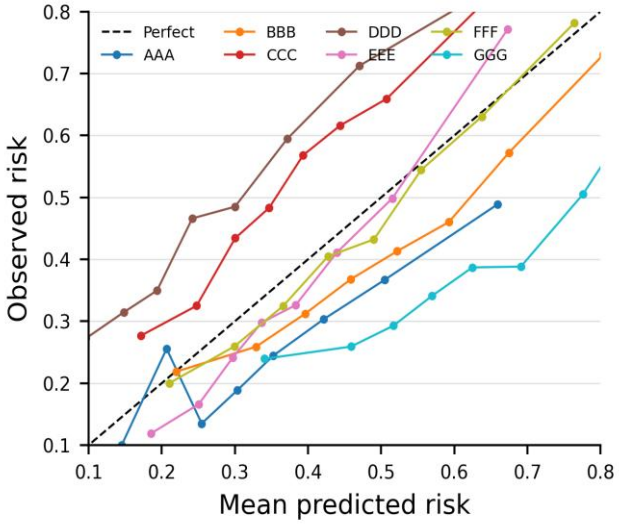

Fig. 4. Reliability of the day-28 VLE-only logistic model in each held-out module.

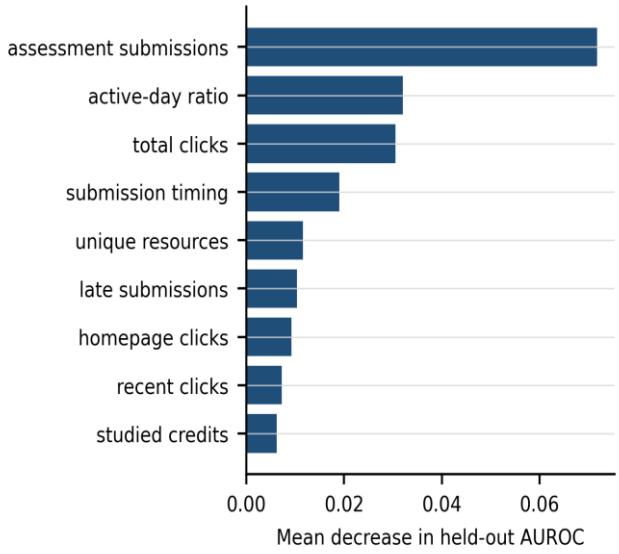

Fig. 5. Weighted permutation importance across day-28 held-out modules for operational logistic regression.

E. Time, Risk-Set Composition, and Errors

The fixed day-28 cohort analysis separated increasing observation length from attrition-induced changes in the active population. For operational logistic regression on the same 27,553 enrollments, AUROC was 0.644 at day 7, 0.665 at day 14, and 0.661 at day 28. The day-28 decline therefore was not explained solely by removal of already-withdrawn learners. For the VLE-only model, AUROC changed from 0.643 to 0.658 to 0.660, while AUPRC increased from 0.569 to 0.594 to 0.604. Submission behavior helped at day 14 but harmed day-28 probability quality, consistent with growing cross-module differences in assessment schedules. More elapsed time did not guarantee better transferable operational features.

At the training-derived decision thresholds, the operational logistic model correctly flagged 76.2 percent of eventual failures and 72.6 percent of withdrawals, but it also flagged 53.8 percent of eventual passes and 47.4 percent of distinctions. These errors caution against treating predicted risk as a deterministic judgment. The output is more appropriate for low-stakes outreach or instructor review than for exclusionary decisions.

F. Feature Importance

Permutation importance for the day-28 operational logistic model identified the number of assessment submissions as the strongest predictor, followed by active-day ratio, total clicks, submission timing, unique resources, and late submissions (Fig. 5). This result should be interpreted as within-held-out-module sensitivity rather than as evidence that feature importance is invariant across modules. The present analysis does not decompose within-module importance from cross-module stability; therefore, the weaker transfer performance observed after adding submission features is compatible with, but does not by itself establish, context-specific importance. A direct within-versus-cross-module importance decomposition would be required to test that mechanism.

V. Discussion

A. Principal Findings

The benchmark provides three answers. For RQ1, both learner identity and course context affected evaluation. Student-disjoint random cross-validation remained optimistic because modules were mixed across folds. The held-out-module design reduced AUROC by 0.055 and exposed materially worse calibration. Under the prespecified hyperparameter settings, logistic regression showed more reliable transfer than the two nonlinear models. This pattern is consistent with prior evidence that strong within-context performance does not guarantee cross-context generalization [6], [7], [10], but the present comparison cannot separate model-class effects from possible undertuning of the nonlinear models. The result does not imply that logistic regression is universally superior; it shows that model ranking depends on the deployment distribution represented by the validation design.

For RQ2, the VLE-only model offered a more defensible transfer point than the broader operational model. Submission variables were individually important, yet adding them reduced cross-module AUPRC and probability accuracy at day 28. Course-specific deadlines, assessment counts, and marking designs can change what a submission means. This is a negative-result contribution: predictive information can be locally useful while degrading transportability. Recorded scores and demographics altered performance again, but their timing and governance costs make them sensitivity conditions rather than default inputs. A feature's availability, stability, and policy acceptability should therefore be evaluated alongside its importance.

For RQ3, calibration and error rates varied sharply across modules. Platt scaling improved pooled logistic metrics only modestly and could not correct module-specific distribution shifts. The GGG fold was especially miscalibrated even though learner overlap was minimal, indicating that the problem was

contextual rather than identity leakage. Furthermore, the fixed-cohort analysis showed that additional weeks did not monotonically improve every specification. The predictive system changes as both the evidence window and the set of still-active learners evolve. Early-warning evaluation should therefore be framed as repeated risk-set prediction rather than a single static classification task.

B. Implications for Learning Analytics Systems

A practical implementation should treat transfer as a gated software lifecycle rather than a one-time model export. A source-trained model can produce provisional risk rankings for a new module, but its probability scale should be monitored against emerging local outcomes. Until enough labeled target data are available, institutions should communicate risk bands or prioritized outreach rather than precise probabilities. When a previous presentation exists, recalibration and threshold selection should use that presentation without contaminating the target evaluation. The benchmark also supports a parsimonious default: engagement variables that have comparable definitions across courses are preferable to assessment and demographic variables whose semantics or acceptability change by context. This sequence—identity-safe validation, destination monitoring, local recalibration, and threshold governance—translates the benchmark into testable requirements for learning-analytics software.

The educational interpretation must remain limited. Clicks and submissions are traces of platform interaction, not direct measures of knowledge, motivation, or ability. False positives may reflect strategic low-click study, prior knowledge, offline work, or inaccessible contextual information; false negatives may reflect sudden work, family, health, or technical events [12]. Explanations should therefore support conversation and resource allocation, not label learners as inherently likely to fail. This human-in-the-loop framing is consistent with calls for transparent, calibrated, and ethically governed predictive analytics [11], [20]–[22].

C. Methodological Contribution

The principal contribution is not a new classifier but a stricter, reusable benchmark specification. It defines the estimand as performance on enrollments from a module absent during training; removes all cross-boundary learner identities; fits preprocessing, calibration, and thresholds inside training data; applies the same nested calibration protocol to the conventional comparator; evaluates active learners at explicit temporal cutoffs; separates feature families by operational legitimacy; and reports discrimination, probability quality, heterogeneity, uncertainty, and explanation. This combination is necessary because a standard dataset does not by itself standardize a valid evaluation [10]. The accompanying scripts produce the cohort, features, folds, predictions, tables, and figures from the verified OULAD tables. The contribution therefore lies in the joint specification of these components: none is claimed as novel in isolation, but their integration makes the deployment estimand, leakage controls, calibration boundary, temporal risk set, and feature-availability constraints explicit within one reproducible benchmark.

D. Limitations

OULAD comes from one distance-learning institution and historical course offerings. Module labels and subject content are anonymized, limiting explanations of why particular modules shifted. VLE records are daily aggregates and omit offline study, motivation, communication outside the platform, and unexpected life events. The final result is a useful operational label but does not measure learning quality or the causal effect of intervention. The evaluated algorithms and fixed hyperparameters do not represent an exhaustive search for maximum predictive performance. Consequently, the lower transfer performance of random forest and histogram gradient boosting cannot be separated from the possibility that those prespecified configurations were undertuned for this setting. The study did not tune models for each target module, use target labels for recalibration, or evaluate interventions. These restrictions make the benchmark conservative but do not establish performance at another institution. Moreover, seven held-out modules are sufficient for a benchmark but not for estimating uncertainty over the wider population of courses; the learner-cluster intervals quantify sampling variation among observed learners, not between-course uncertainty. Expected calibration error is also bin-dependent. Finally, the score-augmented analysis cannot determine exactly when a grade became visible; it should not be interpreted as a prospective score-based deployment result. The feature-importance analysis is also descriptive: it summarizes predictive sensitivity within held-out modules but does not estimate a formal within-module versus cross-module importance decomposition.

VI. Conclusion

Within the OULAD setting examined here, evaluation on an unseen module produced materially different conclusions from student-disjoint cross-validation that mixed module contexts. Student-disjoint random cross-validation substantially overstated performance relative to a student-disjoint held-out-module benchmark even when both designs used the same nested calibration procedure. Under the prespecified hyperparameter configurations, logistic regression transferred better than the evaluated nonlinear models, and VLE-only engagement features achieved nearly identical discrimination with better precision-recall and probability accuracy than a broader assessment-aware specification. Calibration remained module-dependent, so a global correction was insufficient. The resulting evaluation architecture shifts attention from maximizing a pooled score to establishing whether a model is independent, transferable, calibrated, interpretable, and based on legitimate information. These conclusions are limited to seven anonymized modules from a single distance-learning institution and should not be interpreted as evidence of performance across institutions or course populations more broadly. Future work should replicate the benchmark on at least one independent institutional dataset, incorporate systematic hyperparameter tuning within the training boundary, and test whether feature-importance patterns remain stable across source and destination modules.

Data and Code Availability

OULAD is publicly available under the Creative Commons Attribution 4.0 license through the dataset DOI https://doi.org/10.24432/C5KK69 and is described in [1]. The verified analysis used 10,655,280 student-VLE records spanning all 22 module presentations. Reproducible scripts and exact aggregate outputs are supplied with this manuscript; the source data are not redistributed.

Ethics Statement

This secondary analysis used an anonymized public dataset and involved no participant contact, intervention, or attempt at re-identification. Predictions were evaluated as research outputs and were not used to make decisions about individual learners.

Declaration on Generative AI

An OpenAI generative AI tool was used for programming assistance, manuscript drafting, language refinement, and document formatting. The human author specified the research problem and retains responsibility for independently verifying the data, code, analyses, citations, interpretation, and all AI-assisted text before submission.

Dynamic Ant Colony Optimization–Driven Feature Selection for GRU-Based Network Intrusion Detection

Zhaosheng Yang
Department of Information Engineering, Shijiazhuang College of Applied Technology,
Shijiazhuang City, Hebei Province, 050800, China

***Abstract*—Modern network environments generate large-scale, high-dimensional traffic data that can be effectively interpreted as complex temporal signals. Efficiently analyzing such data requires robust feature selection and accurate temporal modeling techniques. In this study, we propose a signal-driven intrusion detection framework that integrates a Dynamic Ant Colony Optimization (DyACO) algorithm with deep recurrent neural modeling. The proposed DyACO performs adaptive wrapper-based feature selection by dynamically adjusting pheromone evaporation, heuristic guidance, and reinforcement strategies to enhance exploration in high-dimensional signal spaces. Selected features are then processed using a gated recurrent unit network to capture temporal dependencies in network traffic signals. The experiments on the CSE-CIC-IDS2018, UNSW-NB15, and NSL-KDD datasets demonstrate that our proposed method not only effectively compresses the feature space but also enhances classification accuracy, precision, recall, and F-score. The results demonstrate that when applied to network traffic, structured temporal signals, along with adaptive optimization modeling, yield an effective solution for intelligent, signal-based anomaly detection.**

Keywords*—Ant colony optimization; feature selection; network intrusion detection; deep learning

I. INTRODUCTION

Nowadays, networked environments produce enormous amounts of diverse traffic data, complicating intrusion detection [1]. Owing to the increasing volume and complexity of cyberattacks, Intrusion Detection Systems (IDSs) face the difficulty of processing highly-dimensional spaces rich in redundant, noisy, and correlated attributes [2]. These factors create challenging classification tasks, high computational requirements, and rising false-positive rates. Similar challenges have also been observed in other security-sensitive domains, where machine learning-based detection approaches require effective feature selection, preprocessing strategies, and imbalance handling mechanisms to improve detection reliability [3]. Moreover, multi-class distributions and class imbalance in standard IDS benchmark sets can further degrade performance because detection results are unbalanced across attack classes. This demonstrates the limited performance of the standard architecture of IDSs under increasing data volume [4].

Feature Selection (FS) is an important technique for improving IDS reliability in high-dimensional network traffic data. Feature Selection is a process of choosing the most relevant features of a dataset [5]. FS enhances efficiency and generalization of the model by discarding the redundant features in the input data [6]. Wrapper-based FS provides an easy way to evaluate classifiers using the subset of features with respect to the original features of the dataset, and it also achieves higher classification performance when compared to filter-based methods [7]. The removal of irrelevant features not only enhances the accuracy of classification models but also reduces their complexity when these models are applied in real time for intrusion detection in large-scale network environments [8].

Despite widespread use, existing wrapper-based and metaheuristic FS approaches exhibit notable shortcomings. Algorithms like GA, PSO, ACO, and CSA, and many of their variants, often suffer from premature convergence, causing the search to get stuck in local optima. Their performance worsens as problem dimensionality increases. In addition, many metaheuristics keep control parameters constant during optimization. The wrapper technique is precise but increases computational time, as it must repeatedly score each possible subset against a classifier.

To address these challenges, it is important to apply optimization algorithms that can adapt their search strategies during execution. Dynamic optimization approaches show that algorithms should detect environmental changes and adjust their search behavior by exploiting previous search knowledge to improve convergence performance [9]. In high-dimensional IDS problems involving FS, the search landscape will be rough and Sparse. The approach needs to adjust dynamically to expand the search region when diversity is required and to shift toward intensified exploitation as the algorithm converges toward the optimal solution. The approach will fail when the algorithms employed have constant parameters, which often results in poor performance as data sets grow.

The Dynamic Ant Colony Optimization (DyACO) algorithm is an adaptive extension of feature selection techniques based on the ACO algorithm, which overcomes the limitations of static search mechanisms (i.e., fixed pheromone evaporation rates, predefined heuristic information, and unchanged transition strategies) in high-dimensional IDS environments. Traditional ACO-based FS techniques usually have fixed pheromone evaporation rates, static heuristic information, and stationary transition rules throughout the entire optimization process. In DyACO, among other mechanisms, heuristic information is dynamic, pheromone evaporation rates vary with iterations, pheromone updates are based on reward and punishment

strategies, and state transition rules are adaptive. Such methods help the algorithm achieve a better balance between exploration and exploitation, prevent pheromone trail stagnation, and improve its capability to discover more compact and discriminative feature subsets. The adaptive parameter control strategy allows DyACO to change its search patterns as the optimization process proceeds, making the feature selection framework less static for high-dimensional IDS datasets, where avoiding local optima and selecting informative attributes are crucial.

Although DyACO was originally designed for continuous optimization tasks, adapting it into a binary framework presents new opportunities for IDS FS. Binary DyACO enables ants to construct inclusion–exclusion vectors representing candidate feature subsets, allowing dynamic search mechanisms to operate in a discrete domain. Embedding this binary DyACO within a wrapper architecture further enhances its utility by enabling direct feedback from classification performance during optimization. Such integration leverages both DyACO's adaptive search strengths and the classifier's discriminative capabilities, resulting in a more refined and practical approach to selecting high-impact features for network intrusion detection.

Based on the aforementioned interests, this work proposes a DyACO-based wrapper FS approach, named DyACO. This algorithm aims to optimize IDSs. DyACO stands out for the following reasons: 1) the proposed algorithm uses an adaptive pheromone function, heuristic function, and transition function for the binary variant of DyACO; 2) the algorithm employs the wrapper approach, combining DyACO for the search process with the CART evaluation function and the GRU classifier for the classifier selection process; 3) the algorithm outperforms current methods in terms of the solutions' compactness, speed of convergence, and detection capabilities on the CIC-IDS2018, UNSW-NB15, and NSL-KDD datasets.

II. Literature Review

Shwaysh, et al. [10] introduced a hybrid IDS model that combines information gain with an autoencoder for dimensionality reduction and an ensemble of gradient-boosted classifiers. Zouhri, et al. [11] proposed a comprehensive comparison of univariate and multivariate filter-based FS methods across a wide array of IDS datasets. Barbosa, et al. [12] developed a filtering technique based on graph modeling of Pareto-dominant, informative, and correlated features. This technique discovers informative features using betweenness centrality on a feature-constructed graph, yielding a compact, discriminative subset with high accuracy using only a few features. Habeeb and Babu [13] proposed a two-level FS method that combines coarse correlation filtering with hybridization of the Whale Optimization Algorithm (WOA) and Genetic Algorithm (GA).

Maseno and Wang [14] proposed a sequential wrapper approach that combines an optimized extreme learning machine with SVM classification. Umer, et al. [15] suggested a wrapper-based FS pipeline integrated with a Multi-Head Attention transformer classifier. Anagha, et al. [16] proposed a framework for jointly incorporating SHAP values, correlation analysis, and information gain to select relevant features in deep learning-based IDS classification tasks. Al-Yaseen, et al. [17] proposed a wrapper method that applies Differential Evolution (DE) for FS and Extreme Learning Machine (ELM) for subset evaluation. Halim, et al. [18] suggested an enhanced GA–based FS strategy with tuned parameters and a novel fitness function to preserve essential information while minimizing dimensionality.

Nazir and Khan [19] introduced a wrapper approach using a Tabu Search (TS) algorithm coupled with an RF process to evaluate feature subsets. Pourardebil Khah, et al. [20] proposed a hybrid multi-phase approach that incorporates heuristic filters, fuzzy TOPSIS, and a Discrete Gray Wolf Optimizer (DGWO) for metaheuristic refinement. Hosseini, et al. [21] proposed a hybrid optimizer for OSMOGA that couples the Slime Mold Algorithm (SMA) with GA, using opposition-based learning to improve GA population diversity. This optimizer provides efficient exploration, along with the exploitation strengths of GA and SMA, ensuring accuracy and accelerating learning within GA for the IDS problem. Laamari and Kamel [22] suggested a multi-objective binary bat algorithm within a wrapper FS framework using Decision Trees (DTs) for evaluation.

Although these studies have demonstrated the effectiveness of feature selection and optimization techniques for IDS, their limitations remain evident. Filter-based approaches generally evaluate features independently and may ignore classifier-related dependencies, while wrapper-based methods provide better classification feedback at the cost of higher computational complexity. Furthermore, optimization-based approaches using GA, PSO, DE, and other metaheuristic algorithms can improve feature selection performance; however, they may suffer from premature convergence, limited adaptability, and difficulty in exploring high-dimensional feature spaces. Hybrid optimization strategies can enhance search capability, but they often introduce additional parameters and computational complexity.

III. Background and Preliminaries

A. Gated Recurrent Neural Networks

Recurrent Neural Networks (RNNs) are commonly used to process temporal data; vanilla RNNs may suffer from unstable gradients and loss of long-term dependencies. Gated Recurrent Units (GRUs) were introduced to address the pitfalls of vanilla RNNs, using an innovative gating mechanism to control information flow over time. As shown in Fig. 1, the main difference between GRUs and LSTMs is that GRUs use both an update gate and a reset gate, which reduces the total number of parameters and helps prevent overfitting. GRUs are an excellent candidate for intrusion detection, given the inherent temporal dependencies in network traffic data and the need for efficient real-time processing. A GRU cell receives an input vector x_t at time step t and combines it with the previous internal state h_{t-1}. The first gating component controls how much past information to preserve. Its activation is computed using a sigmoid-based transformation as expressed in Eq. (1).

$$\Upsilon_t^{(u)} = \sigma(W_u[h_{t-1}, x_t]) \quad (1)$$

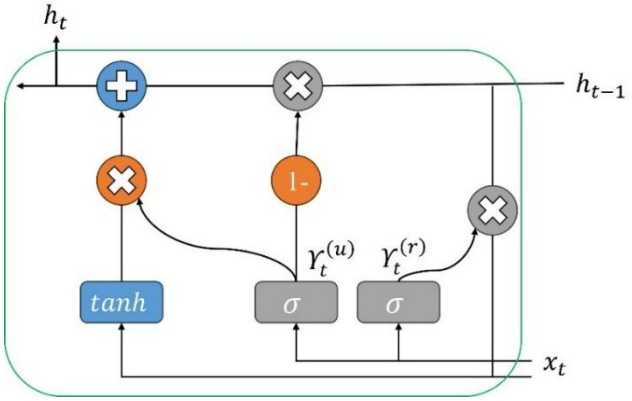

Fig. 1. Internal computational structure of a GRU cell.

The second gate, the reset controller, regulates how much previously forgotten hidden content is used to produce a new candidate state. This mechanism allows the model to selectively ignore irrelevant past information, promoting the sensitivity needed for network attack behaviors with abrupt changes in behavior sequences. Eq. (2) defines the reset gate.

$$r_t^{(r)} = \sigma(W_r[h_{t-1}, x_t]) \tag{2}$$

Using the reset-modulated hidden state, the GRU computes a candidate activation that represents a potential new memory value, incorporating both fresh input and selectively filtered historical data. This candidate is generated via a nonlinear transformation, as expressed in Eq. (3).

$$\widehat{h_t} = tanh\left(W_c\left[r_t^{(r)} \odot h_{t-1}, x_t\right]\right) \tag{3}$$

The final hidden state at a given time step is a function of an interpolation between the preserved old hidden state and the candidate hidden state. This function is modulated by the update gate, which can be viewed as a control gate that enables the cell to maintain a smooth flow of features rather than introduce novelty, as described by Eq. (4).

$$h_t = \left(1 - r_t^{(u)}\right) \odot h_{t-1} + r_t^{(u)} \odot \widehat{h_t} \tag{4}$$

B. Decision Tree Classifier

DTs are hierarchical machine learning algorithms that mimic a human analyst's decision-making process by iteratively dividing a dataset into increasingly homogeneous groups. A DT consists of a root node that is initialized with the dataset, which is later split into branches based on a series of decision statements applied to the values of specific features, one by one. A split within a decision tree occurs on a particular attribute, and the terminal nodes contain the predicted classes, known as leaves.

Several variants of DT algorithms have been developed, including ID3 and C4.5, which employ multiway splits and entropy-based impurity measures. However, these variants can produce overly large structures with deep branching patterns, adding unnecessary complexity. In contrast, the Classification and Regression Tree (CART) methodology uses a binary division strategy, simplifying the tree's architecture and reducing training overhead. CART uses a bottom-up impurity-minimization approach that repeatedly selects the attribute that best separates classes at each node. CART measures split quality using Gini impurity, which assesses the heterogeneity of the class distribution within a subset. For a dataset D consisting of K classes, the impurity is computed using Eq. (5).

$$\text{Gini}(D) = 1 - \sum_{k=1}^{K} \left(\frac{|C_k|}{|D|}\right)^2 \tag{5}$$

where, C_k denotes the collection of samples belonging to class k. A smaller impurity value indicates a more uniform class distribution within the node, thereby signaling a purer partition. When an attribute A is used to divide the dataset into subsets $D_1, D_2, \ldots, D_n$, the overall impurity after splitting is obtained as a weighted combination of the individual impurities, as formulated in Eq. (6).

$$\text{Gini}(D \mid A) = \sum_{i=1}^{n} \left(\frac{|D_i|}{|D|}\right) \text{Gini}(D_i) \tag{6}$$

C. Wrapper Fitness Evaluation

In wrapper-based FS, the search process relies on a scoring mechanism that reflects how well a candidate subset supports classification accuracy while controlling model complexity. Unlike filter approaches, which use statistical proxies, wrapper strategies directly measure a classifier's predictive performance for each subset under evaluation. This lets the optimization algorithm favor feature sets with better real-world detection performance. Because selecting feature sets with very large subset sizes can lead to overfitting and high computational costs, the fitness function must simultaneously weigh predictive accuracy and dimensionality reduction. To formalize this balance, the optimizer assesses each candidate solution using a composite metric that integrates both classification precision and the proportion of selected features. Let P_{cls} represent the accuracy delivered by the classifier (in this case, CART), and let F_{sel} and F_{tot} denote the number of chosen features and the total available attributes, respectively. The resulting fitness score is minimized and is defined in Eq. (7).

$$\text{Fitness} = \min\left[\alpha \cdot \frac{1}{P_{\text{cls}}} + \beta \cdot \frac{F_{\text{sel}}}{F_{\text{tot}}}\right] \tag{7}$$

D. Data Preprocessing Pipeline

Intrusion detection datasets typically contain heterogeneous attributes, missing entries, duplicated flows, and large numerical disparities. If not handled systematically, these irregularities can significantly distort classifier behavior. Therefore, a structured preprocessing workflow is essential to ensure that the learning algorithms receive stable, unbiased, and properly scaled data representations. In this study, a three-stage pipeline comprising data cleansing, categorical encoding, and feature normalization is adopted to prepare all traffic samples for evaluation and optimization.

The first stage focuses on cleaning the raw dataset. Common issues include incomplete records, inconsistent formats, and repeated observations introduced during collection. Eliminating null entries and duplicates ensures that the subsequent optimization process does not overfit to noisy or redundant

patterns. This step is particularly important for intrusion detection since replicated benign flows or malformed attack records can bias the classifier, leading to artificially inflated accuracy or unstable convergence in deep models.

After cleaning, the second stage transforms categorical attributes. Many IDS datasets contain symbolic fields describing protocol categories, service types, connection states, or flag indicators. To incorporate these attributes into numerical learning systems, a translation mechanism is required. In this work, label encoding is applied, assigning a unique integer index to each category.

The third stage addresses feature scaling, a crucial step for stabilizing gradient-based optimization and reducing the influence of attributes with disproportionately large ranges. Large eigenvalue discrepancies can cause erratic cost-surface behavior, producing significant fluctuations during training and slowing model convergence. To mitigate this issue, a min–max normalization scheme is used, mapping each feature value v to a bounded range [0,1]. The transformation is computed according to Eq. (8).

$$v_{norm} = \frac{v - v_{min}}{v_{max} - v_{min}} \tag{8}$$

IV. Proposed Method

The proposed DyACO framework extends classical ACO by integrating dynamic adaptation mechanisms tailored for high-dimensional FS in network intrusion detection. Fig. 2 provides a detailed procedural flow of the DyACO optimization process, beginning with parameter initialization and progressing through iterative solution construction, pheromone updating, and termination. In conventional ACO, pheromone trails, heuristic values, and state-transition rules remain fixed across iterations, often leading to stagnation or premature convergence when searching large binary spaces. To address these limitations, DyACO incorporates four intertwined dynamic mechanisms: adaptive heuristics, iteration-aware pheromone volatility, reward–penalty reinforcement, and parameter-adjusted state transitions.

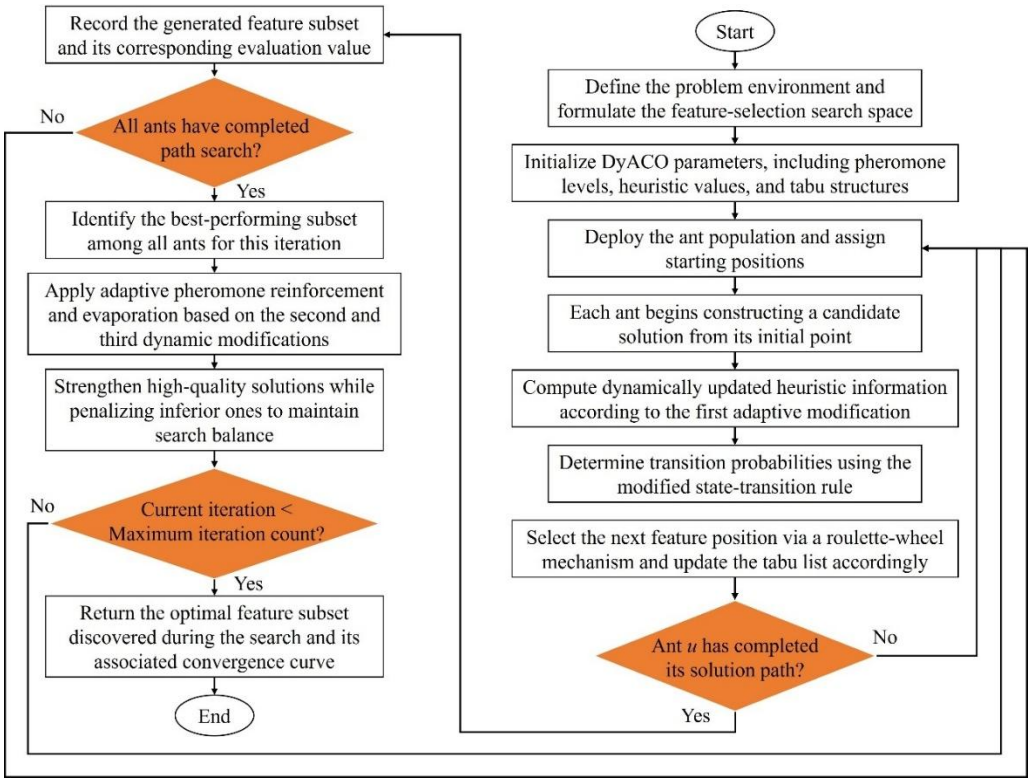

Fig. 2. Flowchart of the DyACO framework.

A. Mathematical Model of Traditional ACO

Traditional ACO simulates cooperative behavior observed in real ant colonies. Artificial ants traverse a solution graph, a graph where selecting or discarding each feature corresponds to choosing one of two nodes, while depositing virtual pheromones that bias future ant decisions. This behavior is characterized by two fundamental processes: the transition probability, which determines how ants choose their next binary decision, and pheromone revision, which regulates the colony's memory. When constructing a feature subset, each ant begins with an empty solution and progressively decides whether to include or exclude each feature. For a given ant u at decision point f, the chance of selecting option o∈{0,1} (exclude/include) is determined by the classical transition model denoted by Eq. (9).

$$\prod_{f,o}^{u} = \begin{cases} \frac{\Lambda_{f,o}(t)^{\alpha_0} \cdot \Gamma_{f,o}(t)^{\beta_0}}{\sum_{o' \in \{0,1\}} \Lambda_{f,o'}(t)^{\alpha_0} \cdot \Gamma_{f,o'}(t)^{\beta_0}} & \text{if } o \text{ is feasible} \\ 0 & \text{otherwise} \end{cases} \tag{9}$$

where, $\Lambda_{f,o}(t)$ is the pheromone intensity for choosing option o for feature f during iteration t, $\Gamma_{f,o}(t)$ is the heuristic

bias for option o, α_0 and β_0 are weight pheromone memory and heuristic guidance, respectively. This formulation governs initial exploration but is insufficient for high-dimensional intrusion datasets because static parameters cannot adapt to evolving search conditions. The pheromone values are updated after each iteration to reinforce desirable decisions. Classical evaporation and deposition follow Eq. (10).

$$\Lambda_{f,o}(t+1) = (1-\delta_0)\Lambda_{f,o}(t) + \sum_{u=1}^{U} \Delta\Lambda_{f,o}^{u}(t) \quad (10)$$

The deposit amount for ant u, is determined by Eq. (11).

$$\Delta\Lambda_{f,o}^{u}(t) = \begin{cases} \frac{C}{L_u} & \text{if ant u selected o for } f \\ 0 & \text{otherwise} \end{cases} \quad (11)$$

where, L_u is the solution quality (e.g., inverse fitness), C is a constant reward, and δ_0 is the fixed evaporation rate. In complex FS scenarios, fixed evaporation and simple reinforcement can cause stagnation due to over-concentration of pheromones on early-discovered subsets.

To overcome the previously described limitations, DyACO introduces adaptive mechanisms that evolve over the course of the search. Rather than treating each decision as static, DyACO continuously adjusts heuristics, pheromone decay, reinforcement, and transition probabilities over iterations.

In classical ACO, heuristic information is often based on simple metrics (e.g., inverse distance). In FS, the "heuristic" should instead reflect a feature's usefulness. DyACO introduces a dynamic weighting function using a Gaussian-shaped modulation that varies with iteration count. The dynamic heuristic is defined in Eq. (12).

$$\Gamma_{f,o}(t) = \Psi_t \cdot \frac{X}{d_{f,o}^2} \quad (12)$$

The temporal scaling factor follows a modified normal distribution, expressed by Eq. (13).

$$\Psi_t = \exp\left(-3\left(\frac{t}{T}\right)^2\right) \quad (13)$$

where, t is the current iteration, T is the maximum number of iterations, $d_{f,o}$ is a domain-specific heuristic score (e.g., relevance measure), and X is a constant. This mechanism ensures strong heuristic guidance early on while diminishing its effect later, promoting better global exploration. Traditional ACO uses a fixed pheromone evaporation parameter, which is unsuitable for high-dimensional FS because it either over-strengthens or over-weakens pheromone memory. DyACO adopts a sigmoid-based dynamic evaporation rate, allowing the pheromone memory to adapt as the search progresses. The dynamic pheromone volatility is computed according to Eq. (14).

$$\delta_t = \frac{1}{1 + e^{-\left(A\cdot\frac{T-t}{T} + B\cdot\frac{t}{T}\right)}} \quad (14)$$

A and B control the transition shape. Early iterations maintain lower evaporation (thus promoting exploitation), while later iterations increase evaporation to encourage diversification and overcome stagnation. Classical reinforcement accumulates pheromone only on good solutions. DyACO modifies this by rewarding strong feature subsets and penalizing the worst ones, encouraging the colony to abandon inferior search regions. The updated pheromone model is expressed in Eq. (15).

$$\Lambda_{f,o}(t+1) = (1-\delta_t)\Lambda_{f,o}(t) + \sum_{u=1}^{U} \Delta\Lambda_{f,o}^{u}(t) \quad (15)$$

The deposit term is adjusted as stated in Eq. (16).

$$\Delta\Lambda_{f,o}^{u}(t) = \begin{cases} \frac{3C}{L_u} + \mu \cdot \frac{L_{best} - L_u}{L_{avg} - L_{best}}, & L_u \le L_{best} \\ \frac{C}{L_u} + \varepsilon \cdot \frac{L_u - L_{worst}}{L_{worst} - L_{avg}}, & L_u \ge L_{best} \\ \frac{C}{L_u}, & \text{otherwise} \end{cases} \quad (16)$$

where, L_{best}, L_{worst}, and L_{avg} are iteration-level statistics, and μ and ε are reinforcement weights. This formulation accelerates convergence while avoiding the amplification of poor decisions. To balance exploration and exploitation, DyACO introduces two mechanisms, namely, the feature-smoothness heuristic and the updated transition rule. A turning-angle heuristic from path planning is reinterpreted here as subset smoothness, discouraging abrupt changes in FS patterns that may lead to unstable learning performance. Its scaling factor is computed using Eq. (17).

$$\Theta_t = \frac{1}{e^{(\omega_t/2)}} \quad (17)$$

where, ω_t quantifies inconsistency in consecutive selections in the current ant's partial feature subset. Eq. (18) presents the improved transition probability combining pheromone, heuristic, and subset-smoothness.

$$\prod_{f,o}^{u}(t) = \begin{cases} \frac{\Lambda_{f,o}(t)^{\alpha_1} \cdot \Gamma_{f,o}(t)^{\beta_1} \cdot \Theta_t^{\gamma_1}}{\sum_{o' \in \{0,1\}} \Lambda_{f,o'}(t)^{\alpha_1} \cdot \Gamma_{f,o'}(t)^{\beta_1} \cdot \Theta_t^{\gamma_1}}, & o \in \{0,1\} \\ 0 & \text{otherwise} \end{cases} \quad (18)$$

A dynamically decaying exploitation parameter q_t is adopted, computed according to Eq. (19).

$$q_t = q^* \cdot \exp\left(-0.5\left(\frac{t}{T}\right)^2\right) \quad (19)$$

B. Training and Evaluation of Classifiers

As a result of the proposed FS procedure, a classification model can be trained to distinguish malicious traffic from legitimate network traffic using the selected features. In this work, a GRU–based neural architecture serves as the primary classifier because it efficiently learns temporal dependencies in flow-based intrusion data. After feature selection, the selected attributes of each network flow are organized by temporal occurrence to construct sequential input representations for the

GRU model. Each traffic sample is therefore represented as a feature sequence, allowing the GRU network to capture temporal dependencies and behavioral patterns associated with different network activities. The trained model is then validated on an independent test partition to assess its generalization ability.

To ensure a fair comparison across competing FS strategies, the same GRU configuration is used throughout the experiments. The implemented intrusion detection network consists of five hidden layers constructed around GRU cells, forming a deep sequential learning pipeline tailored for network traffic analysis. Table I summarizes the architectural specifications, including the number of hidden units, selected feature dimensionality (#), and output class cardinality (*) for each dataset.

TABLE I. HYPERPARAMETER CONFIGURATION OF THE IMPLEMENTED GRU-BASED IDS MODEL

Component	Specification	Value
Input layer	Feature dimension	#
Dense Layer 1	Linear neurons	100
Dense Layer 2	Linear neurons	64
Recurrent Layer 1	GRU cells	256
Recurrent Layer 2	GRU cells	128
Dense Layer 3	Linear neurons	100
Output layer	Linear units (classification)	*
Training batch size	–	1024
Total epochs	–	300
Dropout probability	–	0.5
Learning rate	–	0.0003
Optimization algorithm	–	Adam (Neural Network variant)
Activation function	–	ReLU
Loss function	–	Cross-Entropy

V. RESULTS AND DISCUSSION

This section reports the empirical evaluation of the proposed DyACO framework across two complementary experimental dimensions. First, DyACO is benchmarked using widely adopted optimization test functions from the CEC suite to validate its global search ability and robustness in heterogeneous landscapes. Then, DyACO is assessed within the intrusion detection domain, examining three representative datasets, including CSE-CIC-IDS2018, UNSW-NB15, and NSL-KDD, where its FS efficiency and classification performance are compared against several well-established metaheuristic baselines.

To comprehensively evaluate DyACO, three publicly available benchmark datasets were employed, including CSE-CIC-IDS2018, UNSW-NB15, and NSL-KDD. Collectively, these databases span both legacy and modern network environments, include diverse attack families, and exhibit variations in feature dimensionality and class imbalance, conditions that challenge both FS algorithms and IDS classifiers. The NSL-KDD dataset refines the well-known KDDCup99 dataset by removing redundant and duplicate traffic flows, thereby minimizing training bias and mitigating the dominance of majority attack classes. NSL-KDD contains four attack types and normal traffic instances and provides 125,973 records for training and 22,543 for testing. UNSW-NB15 was generated using the IXIA PerfectStorm testbed to emulate realistic contemporary cyber threats.

CSE-CIC-IDS2018 is an enterprise-grade repository developed by the Canadian Network Security Institute that models realistic operational environments. It includes normal activity, along with a range of modern cyberattacks such as brute-force attacks, infiltration, botnet behavior, Web exploits, and distributed Denial-of-Service (DDoS). Given its high dimensionality and complex traffic dynamics, CSE-CIC-IDS2018 is a particularly rigorous testbed for evaluating advanced FS systems like DyACO. As summarized in Table II, the dataset comprises benign traffic alongside diverse contemporary attack categories.

TABLE II. DISTRIBUTION OF ATTACK CATEGORIES AND FLOW VOLUMES IN THE CSE-CIC-IDS2018 DATASET

Attack category	Example attack instances	Number of flows
Normal traffic	Benign	13,484,708
Web-based exploits	Brute Force-Web, Brute Force-XSS, SQL Injection	611; 230; 87
DoS incidents	SlowHTTPTest, GoldenEye, Slowloris, Hulk	139,890; 41,508; 10,990; 461,192
Infiltration threats	Infiltration	161,934
Brute-force attempts	FTP-BruteForce, SSH-Bruteforce	193,360; 187,589
Botnet activity	Bot	286,191
DDoS-related attacks	HOIC, LOIC-HTTP, LOIC-UDP	686,012; 576,191; 1,730
Overall total	–	16,232,223

In this study, the performance of the GRU-based intrusion classifier, fed with the feature subsets recommended by DyACO, is quantified using a set of well-established metrics derived from the confusion matrix. The confusion matrix summarizes the model's predictions by categorizing samples into four groups: True Positives (TPs) representing correctly detected attacks, True Negatives (TNs) for correctly identified normal traffic, False Positives (FPs) referring to benign samples incorrectly flagged as malicious, and False Negatives (FNs) denoting attacks that the classifier failed to identify. To comprehensively evaluate the classifier, four primary measures are adopted: accuracy, recall, precision, and F1-score. Accuracy reflects the overall proportion of correctly classified samples and serves as a broad indicator of predictive performance, computed using Eq. (20).

$$ACC = \frac{TP + TN}{TP + TN + FP + FN} \tag{20}$$

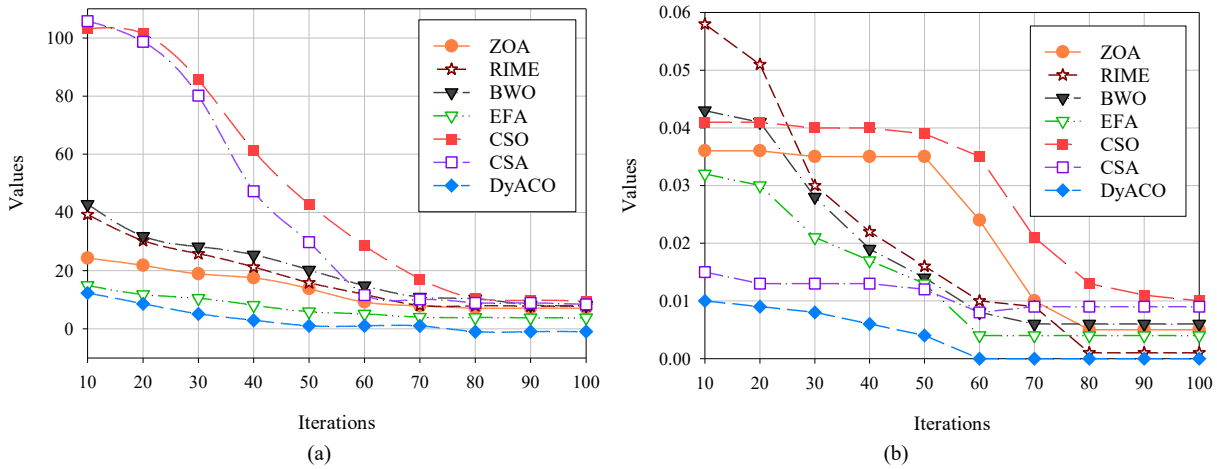
To better capture the algorithm's ability to identify malicious behavior, recall [(Eq. (21)] is employed. Recall quantifies the fraction of actual attacks the algorithm detects.

$$Recall = \frac{TP}{TP + FN} \quad (21)$$

Complementing recall, precision measures the reliability of positive predictions by evaluating how many detected attacks are indeed malicious. It is calculated according to Eq. (22).

$$Precision = \frac{TP}{TP + FP} \quad (22)$$

Since high recall with low precision (or vice versa) is undesirable, the F1-score provides a harmonic mean of these two metrics, yielding a balanced indicator of IDS performance. Eq. (23) defines the F1-score.



$$F1 = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (23)$$

To establish the optimization capability of DyACO, the framework was initially benchmarked using a collection of well-known continuous test functions widely adopted in CEC competitions. As summarized in Table III, these functions span diverse search landscapes, varying in modality, curvature, and search-space boundaries. DyACO was evaluated against six competitive baseline optimizers, including Zebra Optimization Algorithm (ZOA) [23], Rime Optimization Algorithm (RIME) [24], Beluga Whale Optimization (BWO) [25], Enhanced Fireworks Algorithm (EFA) [26], Chicken Swarm Optimization (CSO) [27], and Crow Search Algorithm (CSA) [28]. All experiments used uniform settings, including a population size of N=60, a 30-dimensional search space, and a maximum of 100 iterations.

TABLE III. BENCHMARK OPTIMIZATION FUNCTIONS USED IN THIS STUDY, ALONG WITH THEIR INPUT DOMAINS AND GLOBAL SOLUTIONS

Benchmark	Reformulated expression	Search interval	Optimal value
Rosenbrock	$g(\mathrm{u}) = \sum_{j=1}^{m-1} [100(u_{j+1} - u_j^2)^2 + (1 - u_j)^2]$	$[-5, 10]$	0
Schaffer	$g(v_1, v_2) = 0.5 + \frac{\sin^2(v_1^2 - v_2^2) - 0.5}{[1 + 0.001(v_1^2 + v_2^2)]^2}$	$[-100, 100]$	0
Booth	$g(v_1, v_2) = (v_1 + 2v_2 - 7)^2 + (2v_1 + v_2 - 5)^2$	$[-10, 10]$	0
Easom	$g(v_1, v_2) = -\cos(v_1)\cos(v_2)\exp(-[(v_1 - \pi)^2 + (v_2 - \pi)^2])$	$[-100, 100]$	–1
Rastrigin	$g(\mathrm{u}) = 10m + \sum_{j=1}^{m} [u_j^2 - 10\cos(2\pi u_j)]$	$[-5.12, 5.12]$	0
Ackley	$g(\mathrm{u}) = -20\exp(-0.2\sqrt{\frac{1}{m}\sum_{j=1}^{m} u_j^2}) - \exp(\frac{1}{m}\sum_{j=1}^{m}\cos(2\pi u_j)) + 20 + e$	$[-5, 5]$	0

Fig. 3 visually presents convergence behavior and final optimization performance, highlighting the superiority of the proposed method. The intrusion detection experiments on CSE-CIC-IDS2018, UNSW-NB15, and NSL-KDD collectively demonstrate DyACO's effectiveness in improving FS quality and classification performance across heterogeneous network environments. DyACO consistently outperforms baseline metaheuristics, demonstrating its ability to navigate high-dimensional search spaces while maintaining stable convergence. The visual comparisons in Fig. 4–7 further reinforce these findings by clearly separating DyACO from competing strategies across accuracy, precision, recall, and F1-score distributions.

VI. Conclusion

In this study, a dynamic wrapper-based method called DyACO, based on the ACO algorithm, is proposed to efficiently address high-dimensional FS problems for NID. By introducing adaptive heuristics, iteration-dependent pheromone evaporation rates, magnitude-based reward–penalty functions in the reinforcement scheme, and adaptive state transition rules, the DyACO algorithm overcomes the limitations of conventional metaheuristic algorithms. Experimental evaluations on the CSE-CIC-IDS2018, UNSW-NB15, and NSL-KDD datasets demonstrate that DyACO can obtain compact subsets of discriminative features, reduce feature dimensionality, and achieve high detection performance. Based on accuracy, precision, recall, and F1-score, DyACO demonstrates superior performance compared with the considered optimization algorithms while maintaining the computational efficiency required for wrapper-based methods.

***Abstract*—This study proposes an integrated data-driven framework that couples wind power forecasting with the operational optimization of wind turbines under real meteorological conditions. Unlike conventional approaches that focus primarily on improving the predictive accuracy of energy production models, the proposed framework extends forecasting toward proactive operational decision-making, establishing a direct link between prediction, turbine operation, and energy output. Machine learning techniques are used to model the complex nonlinear relationships between meteorological variables and turbine power output, after which a grid-based optimization procedure identifies the operating conditions that maximize generation. The framework is evaluated on ten years of meteorological data for Kosovo covering the period 2015–2024, providing an empirical basis for assessing its applicability. Particular attention is given to identifying the most influential operational and environmental parameters and to determining optimal operating conditions under varying wind regimes. Feature-importance analysis indicates that wind speed and wind direction dominate the response of the model, while rotor speed and blade pitch contribute almost as strongly as the external conditions. Applying the optimization layer to the predicted operating points yields an average increase in power output of 73.70 kW, corresponding to an estimated annual energy gain of approximately 645.60 MWh. A comparative evaluation further shows that a recurrent architecture based on Long Short-Term Memory achieves substantially lower forecasting error than the Random Forest model employed for optimization. The main contribution of the study is a unified forecasting–optimization framework that moves beyond predictive accuracy toward measurable performance improvement, and that can serve as a practical decision-support tool for wind farm operators.**

***Keywords*—Wind energy; wind power forecasting; machine learning; operational optimization; wind turbine performance; random forest; long short-term memory**

I. Introduction

The integration of wind energy into modern power systems is constrained less by the availability of the resource than by its variability. Because the power delivered by a turbine responds nonlinearly to a set of interacting meteorological variables, system operators require reliable estimates of production in order to schedule generation, balance the network, and limit curtailment. A substantial body of work has therefore been devoted to wind power forecasting, ranging from classical statistical models to modern machine learning and deep learning architectures [1]–[4].

The dominant evaluation paradigm in this literature is statistical: competing models are ranked according to how closely their predictions match observed production, using error measures such as the mean absolute error, the root mean squared error and the coefficient of determination. This paradigm has produced considerable methodological progress, but it leaves an important question unanswered. A forecast, however accurate, does not by itself increase the energy delivered by a turbine; it acquires value only when it is translated into an operating decision. Comparatively little attention has been paid to the step that connects the two, namely the use of a trained predictive model as a surrogate over which turbine control parameters can be searched.

The present study addresses this gap by developing a unified forecasting–optimization framework and evaluating it on real meteorological data for Kosovo covering the period 2015–2024. A Random Forest regressor is first trained to predict power output from meteorological and operational variables. The trained model is then used in a second phase as an objective function: for every instance in the test set, combinations of rotor speed and blade pitch are evaluated and the combination that maximizes predicted output is retained. The difference between the power predicted under the current control setting and the power predicted under the optimized setting is reported both instantaneously, in kW, and as an estimated annual energy gain, in MWh.

A. Research Objectives

To achieve this aim, the following objectives were defined:

- To assemble and prepare real meteorological data for Kosovo for the period 2015–2024;
- To develop an accurate model for forecasting power output;
- To optimize the key turbine control parameters, specifically rotor speed and blade pitch;
- To quantify the resulting energy gains in kW and in MWh per year;

- To compare the results obtained with reference studies on wind power forecasting.

B. Contribution of this Study

The contribution of the work is threefold. First, it formulates operational optimization as a search performed directly over a trained forecasting model, so that prediction and control are treated within a single computational pipeline rather than as separate exercises. Second, it quantifies the outcome of that search in physical rather than purely statistical units, expressing the benefit as an average power increment and an estimated annual energy gain. Third, it evaluates the framework on a ten-year meteorological record for Kosovo, a setting characterized by light to moderate wind conditions in which precise turbine control is particularly consequential.

C. Organization of the Study

The remainder of the study is organized as follows. Section II reviews related work on statistical, machine learning, and deep learning forecasting models and on optimization in wind energy systems. Section III describes the data, the construction of the model variables and the proposed forecasting–optimization methodology. Section IV reports the experimental results. Section V discusses their interpretation, implications, and limitations, and Section VI concludes.

II. Related Work

A. Statistical Forecasting Models

Classical time-series approaches remain a standard benchmark in wind power forecasting. The Box–Jenkins family of autoregressive integrated moving average models, including its seasonal variant, provides a well-established framework for representing linear temporal dependence [2], while general methodological guidance for the construction and evaluation of such models is given by Hyndman and Athanasopoulos [3]. Decomposition-based procedures such as Prophet, which describe a series through additive trend, seasonality, and holiday components, have been proposed as robust and easily configurable alternatives [4]. Because these formulations assume approximately linear relationships, their accuracy tends to degrade when the underlying atmospheric processes are strongly nonlinear. The importance of rigorous out-of-sample evaluation in this setting has long been emphasised [16], and broader reviews situate deterministic forecasting within the wider move toward probabilistic energy forecasting [1].

B. Machine Learning Approaches

Ensemble methods based on decision trees are widely used for wind power prediction because they capture nonlinear interactions without requiring an explicit functional form. The Random Forest algorithm aggregates a large number of decorrelated trees and provides, as a by-product, a measure of the relative importance of each input variable [5]. Wei et al. applied this approach to SCADA records for short-term wind power forecasting and reported competitive accuracy relative to conventional baselines [6]. Kernel-based regression constitutes a second established family: support vector regression [7], [8] performs well on moderately sized datasets.

Although its accuracy depends strongly on the selection of the regularisation and kernel parameters, practical guidance has been developed [9].

C. Deep Learning Approaches

Recurrent neural networks with gated memory cells were introduced to address the vanishing-gradient problem that limits the modelling of long-range temporal dependence [10], and a systematic evaluation of the architectural variants of this family is provided by Greff et al. [11]. Applications to wind power are numerous: Liu et al. demonstrated that a Long Short-Term Memory network outperforms conventional statistical baselines on short-horizon forecasting [12], while hybrid formulations that combine a linear model with a recurrent network have been proposed to capture linear and nonlinear structure simultaneously [13]. Convolutional recurrent architectures extend the same principle to spatio-temporal fields [14].

D. Optimization in Wind Energy Systems

Optimization has traditionally been applied in wind energy at the design stage, for instance in the placement of turbines so as to maximize the energy captured across a site [15]. Operational optimization at the level of an individual turbine, in which control parameters are adjusted in response to predicted conditions, has received considerably less attention in the data-driven literature. The present study is positioned at this intersection: it retains the forecasting model as the analytical core, but treats it as a surrogate over which an operating decision is searched, thereby linking the two strands of research described above.

III. Materials and Methods

A. Study Area and Data Source

The meteorological data used in this study were obtained from the renewables.ninja platform for the territory of the Republic of Kosovo and cover the ten years from 2015 to 2024. The retrieved variables comprise wind speed, temperature, humidity, and air density. Fig. 1 presents the statistical distribution of wind speed over the observation period. The distribution follows the Weibull form that is characteristic of wind energy studies, with a high concentration of observations at low and moderate speeds. The modal wind speed lies between approximately 0.8 and 1.2 m/s, and although the majority of measurements fall below 4 m/s, the distribution exhibits a long right tail extending to between 6 and 8 m/s. It is this tail that accounts for the greater part of the energy that can be extracted, since the available power scales with the cube of wind speed. The high absolute frequencies, reaching approximately 16,000 observations in the modal bin, indicate that the models were trained on a sufficiently large sample.

The wind regime shown in Fig. 1 has a direct bearing on the design of the study. Under light to moderate conditions, the operating point of a turbine lies for much of the time on the steep part of the power curve, where small changes in blade pitch and rotor speed translate into comparatively large changes in output. This is precisely the regime in which an optimization layer is expected to be most valuable.

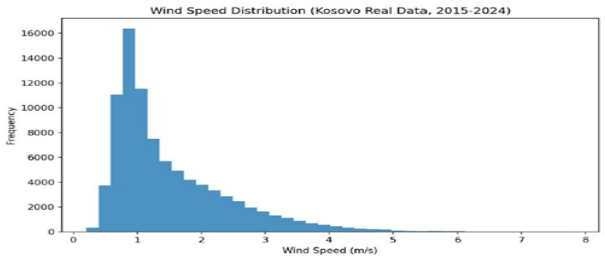

Fig. 1. Statistical distribution of wind speed in Kosovo over the period 2015–2024.

B. Data Preparation

The raw records were harmonised on a common timestamp, filtered to the period 2015–2024, and arranged in time-series format. This procedure ensures the quality and internal consistency of the dataset and provides a uniform temporal resolution for the subsequent modelling stages.

C. Construction of the Model Variables

The variables of the final dataset are summarised in Table I. The pressure variable was not measured directly but derived from the ideal gas law, which links temperature and air density. Because complete SCADA records were not available for the site, the power output, rotor speed and blade pitch variables were modelled so as to reproduce the characteristic operating behaviour of a wind turbine. This is an acknowledged constraint of the present work and is discussed in Section V-D.

TABLE I. VARIABLES OF THE FINAL MODELLING DATASET

Variable	Description	Role
Timestamp	Time index of the observation	Index
WindSpeed	Horizontal wind speed	Predictor
WindDirection	Direction of the incident flow	Predictor
Temperature	Ambient air temperature	Predictor
Humidity	Relative air humidity	Predictor
Pressure	Derived from the ideal gas law	Predictor
RotorSpeed	Rotational speed of the rotor	Control
BladePitch	Pitch angle of the blades	Control
TurbineStatus	Operating state of the turbine	Auxiliary
PowerOutput	Electrical power delivered	Target

D. Train–Test Partition

The dataset was partitioned chronologically, with random shuffling explicitly disabled. Preserving the temporal ordering of the observations is essential in a time-series setting: a random partition would allow information from later periods to influence the fitted model and would therefore produce optimistically biased estimates of out-of-sample accuracy through data leakage.

E. Phase One: the Forecasting Model

The first phase of the framework trains a Random Forest regressor to predict power output from the meteorological and operational variables listed in Table I. The algorithm constructs an ensemble of decision trees and aggregates their individual predictions, which yields three properties that are relevant here: it captures nonlinear relationships without an explicit functional specification; it is robust to noise in the input data; and it provides an interpretable ranking of variable importance [5].

F. Phase Two: Grid-Based Operational Optimization

The second phase reuses the trained model as an objective function. Let $\hat{f}$ denote the fitted regressor, x_t the vector of meteorological conditions observed at time t, and ω and β the rotor speed and blade pitch, respectively. For each instance of the test set, a systematic search is performed over a discrete grid of admissible control values, and the combination that maximises the predicted output is retained:

$$(\omega^*, \beta^*) = \arg\max \hat{f}(x_t, \omega, \beta) \quad (1)$$

The instantaneous benefit of the optimization at time t is the difference between the power predicted under the optimized setting and the power predicted under the control setting actually applied:

$$\Delta P_t = \hat{f}(x_t, \omega^*, \beta^*) - \hat{f}(x_t, \omega_t, \beta_t) \quad (2)$$

The corresponding annual energy benefit is obtained by extrapolating the mean gain over the hours of a full year:

$$E = \Delta\bar{P} \times 8760 / 1000 \quad (3)$$

where, E is expressed in MWh per year and $\Delta\bar{P}$ in kW. Grid search was preferred over gradient-based alternatives because the control space is low-dimensional and bounded, which makes an exhaustive evaluation computationally inexpensive while guaranteeing that the returned solution is globally optimal on the grid. This step transforms the model from a forecasting instrument into a decision-support instrument.

G. Evaluation Metrics

The predictive accuracy of the models was assessed using three standard measures. The mean absolute error reports the average magnitude of the deviations:

$$MAE = (1/n)\ \Sigma\ |y_i - \hat{y}_i| \quad (4)$$

The root mean squared error penalises large deviations more heavily, since the errors are squared before averaging:

$$RMSE = \sqrt{[\ (1/n)\ \Sigma\ (y_i - \hat{y}_i)^2\ ]} \quad (5)$$

The coefficient of determination expresses the proportion of the variance of the observed series that is explained by the model:

$$R^2 = 1 - \Sigma\ (y_i - \hat{y}_i)^2\ /\ \Sigma\ (y_i - \bar{y})^2 \quad (6)$$

In addition to these metrics, the effect of the optimization layer was quantified through the average power gain in kW and the estimated annual energy gain in MWh per year, as defined in Eq. (2) and (3).

IV. RESULTS

A. Relative Importance of the Input Variables

Fig. 2 reports the relative contribution of each input variable to the predictions of the Random Forest model. Wind speed emerges as the dominant predictor, with an importance above 0.175, which confirms that the model correctly identifies the primary physical driver of power output. Wind direction ranks

second, indicating that the alignment of the rotor with the incident flow is also material to performance.

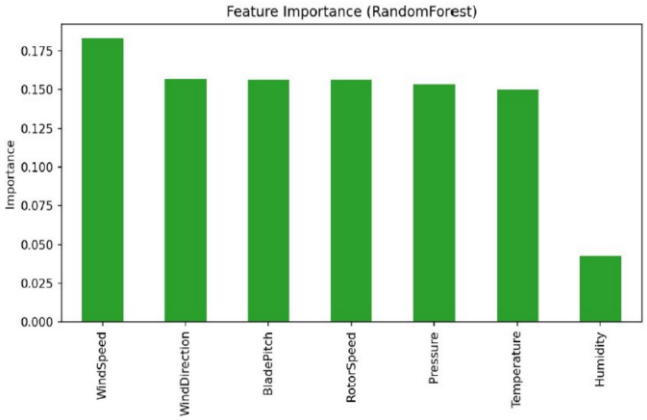

Fig. 2. Distribution of feature importance obtained from the Random Forest model.

The two control variables, blade pitch and rotor speed, exhibit almost equal importance at approximately 0.15. This result is central to the argument of the study: the internal control of the turbine carries nearly as much weight in determining the output as the external atmospheric conditions, which provides an empirical justification for treating these two parameters as decision variables. Pressure and temperature have a comparable influence, consistent with their role in determining air density, whereas humidity is the least influential input, with an importance below 0.05. The ranking as a whole is physically coherent, which supports the view that the fitted model is well behaved rather than merely well fitted.

B. Effect of Operational Optimization on Power Output

Fig. 3 compares the power predicted under the control setting currently applied with the power predicted under the optimized setting, over the final segment of the test period. Under the current setting, the output fluctuates between approximately 20 kW and 40 kW, with isolated excursions to about 65 kW. Under the optimized setting, the series operates in a band between roughly 100 kW and 120 kW.

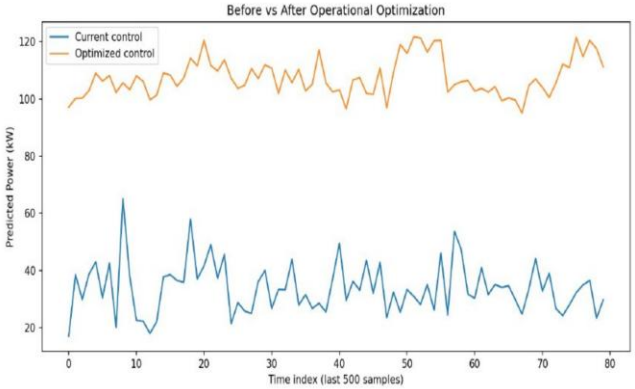

Fig. 3. Predicted power output before and after operational optimization.

Two features of Fig. 3 deserve comment. The first is the magnitude of the shift: the mean output rises from approximately 35 kW to above 105 kW over the segment shown. The second is the change in the character of the series. The optimized trajectory not only lies higher but is also more stable, in the sense that the extended intervals of depressed output visible in the baseline are absent. The optimization therefore acts less as a uniform additive gain than as the removal of a set of low-performance operating states.

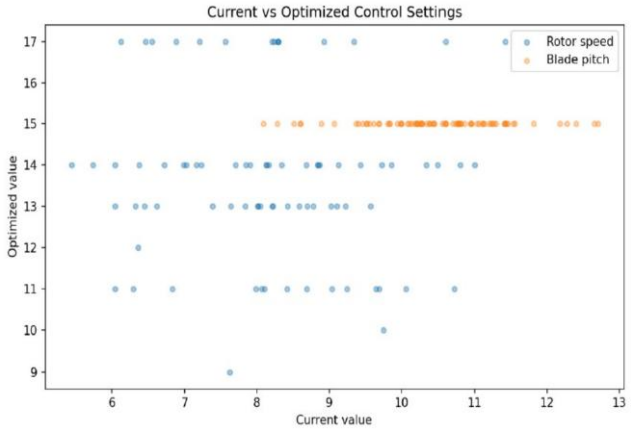

Fig. 4. Current and optimized values of rotor speed and blade pitch.

Fig. 4 examines the control settings that produce this result, plotting the optimized value of each parameter against the value currently applied. The rotor speed points are widely dispersed, indicating that the search adjusted the rotational speed dynamically; the optimized values nevertheless concentrate at the upper end of the admissible range, between approximately 13 and 17, largely irrespective of the starting value. The blade pitch points display a different and more striking pattern: the optimized values converge on a value of approximately 15 across the whole range of current settings, which span roughly 8 to 13.

The convergence of the pitch angle suggests that the baseline control regime was operating away from the point that the model identifies as optimal for the prevailing conditions, and that a fixed angle of approximately 15 units represents the most favourable configuration for energy capture in this wind regime. Taken together, the two panels describe a transition from a broadly distributed, reactive control pattern to a narrow and targeted one.

The aggregate effect of the optimization is summarised in Table II. The average instantaneous gain of 73.70 kW corresponds, through Eq. (3), to an estimated annual energy benefit of 645.60 MWh.

TABLE II. SUMMARY OF THE ENERGY GAIN OBTAINED FROM OPERATIONAL OPTIMIZATION

Indicator	Value	Unit
Mean baseline power (test segment)	35	kW
Mean optimized power (test segment)	105	kW
Average power gain	73.70	kW
Estimated annual energy gain	645.60	MWh/year
Optimized blade pitch (modal)	15	deg
Optimized rotor speed (range)	13–17	rpm

C. Comparative Statistical Performance

Fig. 5 compares the forecasting model and the optimization model across the three evaluation metrics on a normalised scale on which higher values denote better performance. The forecasting model attains the maximum normalised value of 1.0 for both MAE and RMSE, whereas the optimization model operates close to 0.0 on the same axes.

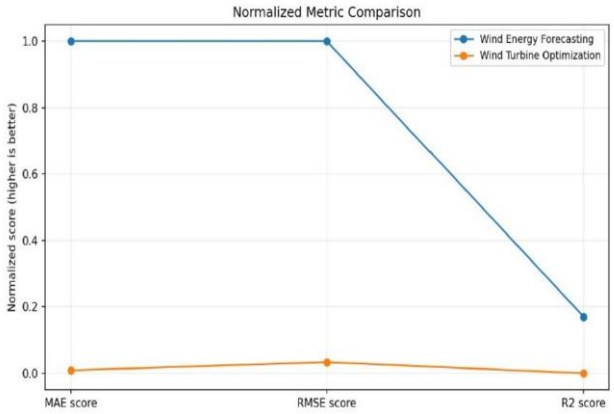

Fig. 5. Normalized comparison of statistical performance between the forecasting model and the optimization model.

This contrast should be interpreted with care. It does not indicate that the optimization model is defective, but rather that the two models are solving different problems: reproducing an observed series is an intrinsically easier task than searching a control space in which variability is substantially higher. The comparatively low R^2 values obtained by both models, relative to their error-based scores, indicate that although the absolute magnitude of the errors is controlled, a large share of the variance of the target remains unexplained. This is consistent with the stochastic character of wind.

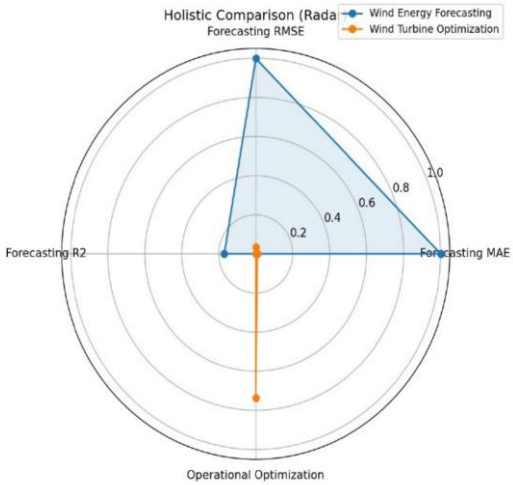

Fig. 6. Radar summary of forecasting accuracy and operational improvement for the two models.

Fig. 6 presents the same comparison in radar form, adding an axis for operational improvement. The forecasting model occupies a large area on the accuracy axes but contributes little on the operational axis, whereas the optimization model displays the complementary profile, extending strongly toward operational improvement while remaining modest on the statistical axes.

The two profiles are best read as describing a division of labour rather than a ranking. The forecasting model supplies the calibrated representation of the environment in which the turbine operates; the optimization layer converts that representation into an operating decision. Neither component delivers the reported gain on its own.

D. Comparison of the LSTM and Random Forest Models

Fig. 7 reports a quantitative comparison of the Long Short-Term Memory network used for forecasting and the Random Forest model used for optimization, in the original units of the error metrics. The LSTM attains error values close to zero on both MAE and RMSE, confirming the suitability of gated recurrent architectures for wind energy time series. The Random Forest model records higher errors, of the order of 38 for MAE and 47 for RMSE. The numerical values are summarised in Table III.

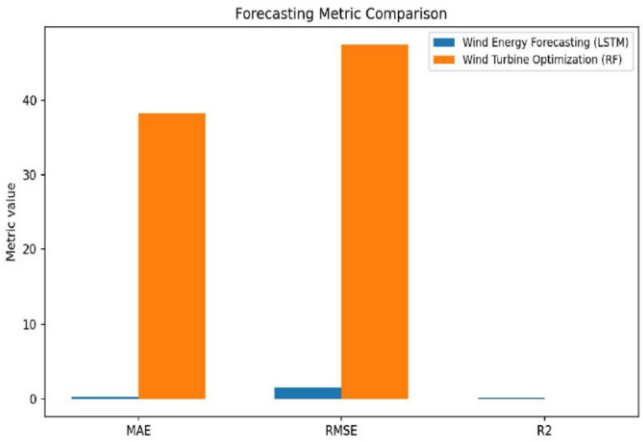

Fig. 7. Comparative error performance of the LSTM and Random Forest models.

TABLE III. COMPARATIVE FORECASTING PERFORMANCE OF THE TWO MODELS

Model	MAE	RMSE	R^2
LSTM (forecasting)	0	0	low
Random Forest (optimization)	38	47	low

The difference in error magnitude is expected given the roles assigned to the two models. The recurrent network is trained exclusively to reproduce a temporal signal, whereas the ensemble model is required to generalise across a control space that is explored counterfactually, at operating points that were never observed. The lower R^2 values recorded by both models reflect the difficulty of explaining the full variance of wind-driven output rather than a deficiency specific to either architecture.

V. DISCUSSION

A. Forecasting Accuracy Versus Operational Value

The results reported above are consistent with the established finding that nonlinear models are better suited to

wind power prediction than linear alternatives, because atmospheric processes are themselves nonlinear and require flexible functional forms to be represented adequately. Linear specifications remain valuable for their simplicity and interpretability, but they do not capture the full complexity of the system.

At the same time, the study shows that even advanced models do not achieve uniformly strong performance: the negative coefficient of determination obtained in the case study reflects a high level of uncertainty in the wind data and confirms that forecasting remains a difficult problem in this setting. The significance of this observation lies in what follows from it. Although the forecasting model is imperfect in a statistical sense, it still supports an operational decision that produces a measurable gain. The value of a model in this context is therefore not exhausted by its statistical accuracy; its practical applicability constitutes a distinct and equally relevant criterion.

B. Integration of the Two Approaches

A forecasting-oriented study is concerned with building and comparing models, evaluates them with statistical metrics, and aims at improving predictive accuracy. Such work is methodologically strong, well suited to benchmarking and provides a solid theoretical foundation, but it does not guarantee any direct improvement in energy production and remains at an analytical level. An optimization-oriented study combines forecasting with a search over the control space, focuses on operational decision-making and generates measurable energy gains, at the cost of depending on the quality of the underlying forecasting model and of requiring greater implementation complexity. Table IV summarises this comparison.

TABLE IV. FORECASTING-ORIENTED AND OPTIMIZATION-ORIENTED APPROACHES

Aspect	Forecasting-oriented	Optimization-oriented
Objective	Predictive accuracy	Operational decision
Evaluation	Statistical metrics	Energy gain in kW, MWh
Strength	Benchmarking, theory	Practical applicability
Limitation	No direct gain	Depends on forecast quality
Output	Predicted series	Control set-points

The central claim of this study is that these two approaches are complementary rather than competing. Forecasting supplies an estimate of future conditions; optimization uses that estimate to select an operating point. Their combination constitutes an integrated decision-support system in which the model predicts production, the optimization layer adjusts the operational parameters, and the resulting configuration delivers higher performance than either component would achieve in isolation.

C. Implications for the Kosovo Power System

In the context of Kosovo, where the renewable generation portfolio is still developing, the framework has practical relevance. Data-driven operational management of the kind described here can contribute to increasing the efficiency of installed turbines, reducing energy losses, improving the stability of the network and supporting decarbonisation policy. These considerations apply in particular to existing installations such as the Bajgora and Kitka wind farms, provided that sufficient operational and meteorological data are made available for model calibration.

D. Limitations

Four limitations should be borne in mind when interpreting the results. First, complete SCADA records were not available, and the power output, rotor speed and blade pitch series were therefore modelled rather than measured; the reported gains consequently describe the behaviour of the model under a simulated operating regime and require confirmation against instrumented data. Second, the optimization is performed within the trained model, so the estimated gains are conditional on the fidelity of that model and cannot be interpreted as measured production increases. Third, the coefficient of determination obtained in the case study is low and in places negative, which places a clear bound on the confidence that can be attached to individual point forecasts. Fourth, the analysis covers a single site and a single turbine configuration, so the generalisability of the reported set-points to other wind regimes remains to be established.

VI. CONCLUSION

This study has integrated machine learning-based forecasting with the operational optimization of wind turbines, providing a coherent framework for the data-driven management of renewable energy systems. The results indicate that advanced nonlinear models, and in particular Long Short-Term Memory networks, capture the complex temporal dependencies and high variability of wind power generation more effectively than conventional statistical approaches. The superior performance of the recurrent architecture demonstrates that forecasting can be substantially improved when temporal dependence and nonlinearity are modelled explicitly.

The addition of an operational optimization layer over the rotor speed and blade pitch parameters further demonstrates that the practical value of a forecasting model should not be assessed solely by its statistical accuracy. Even where forecasting uncertainty persists, the predicted operating conditions can be used to identify beneficial turbine configurations. In the present case, the optimization yielded an average increase in power output of 73.70 kW, corresponding to an estimated annual energy gain of approximately 645.60 MWh.

Forecasting and data-driven optimization should therefore not be regarded as competing approaches. Their integration provides a decision-support framework capable both of predicting future generation and of identifying the operating conditions associated with improved turbine performance. The findings are particularly relevant in the context of Kosovo, where the efficient use of renewable resources supports energy security, grid integration and the reduction of losses and emissions.

Future work should extend the framework to larger and instrumented datasets, incorporate additional turbine operating parameters, adopt uncertainty-aware forecasting methods, and examine real-time optimization under changing environmental and grid conditions. Such developments would strengthen both the applicability and the scalability of integrated machine

learning and optimization approaches for sustainable wind energy management.

ATLAS-FL: Active Timing-Adversary-Resilient Secure Aggregation for Gateway-Assisted IoT, IIoT, and IoMT Federated Intrusion Detection

Mohammad Othman Nassar
Faculty of Information Technology - Cyber Security Department, Amman Arab University, Amman, Jordan

***Abstract*—Federated learning (FL) enables distributed intrusion detection without centralizing raw Internet of Things (IoT), Industrial IoT (IIoT), or Internet of Medical Things (IoMT) traffic. Secure aggregation protects update contents, but it does not authenticate the temporal context in which a protected contribution is admitted. An active network adversary may delay, suppress, replay, or slot-shift otherwise valid submissions, thereby shaping the accepted cohort, inflating survivor weights, and exposing participation through release traces. This study presents ATLAS-FL, an authenticated temporal-integrity layer for masking-based secure aggregation. The protocol binds client identity, round, slot, timing window, fresh nonce, and ciphertext digest through the Hash-based Message Authentication Code using SHA-256 (HMAC-SHA256); performs replay-cache and slot-consistency checks before Bonawitz-style mask recovery; fixes aggregation weights before arrivals are observed; and releases a fixed-length envelope at a committed time. A formal game-based analysis reduces temporal-binding forgery and cross-round replay to HMAC unforgeability and hash collision resistance, while proving no post-hoc survivor-weight inflation under the fixed-weight rule. The evaluation replicates the same protocol across Edge-IIoTset, N-BaIoT, CICIoMT2024, and WUSTL-EHMS-2020 and introduces FedBuff and FedBuff-SecAgg to separate benign straggler tolerance from adversarial timing integrity. Under the twenty-run profile, ATLAS-FL retains attacked macro-F1 of 93.1 ± 0.4% on Edge-IIoTset, 95.8 ± 0.3% on N-BaIoT, 94.9 ± 0.4% on CICIoMT2024, and 94.2 ± 0.5% on WUSTL-EHMS-2020. Accepted manipulated events remain at or below 6.8%, participation-inference area under the receiver operating characteristic curve (AUC) falls to 0.53 ± 0.02, and weight inflation falls from 0.310 to 0.018 with 5.9% round-latency and 2.8% communication overhead at the evaluated cohort size.**

Keywords*—Federated learning; secure aggregation; active timing adversary; IoT intrusion detection; IIoT security; Internet of Medical Things; buffered asynchronous aggregation; differential privacy

I. INTRODUCTION

Intrusion evidence in Internet of Things (IoT), Industrial Internet of Things (IIoT), and Internet of Medical Things (IoMT) systems, including devices, gateways, industrial controllers, hospital monitoring centers, and edge services, can be collected in a centralized manner. This practice facilitates model training but increases costs associated with data exchange, while also potentially exposing operational or healthcare-related traffic. Federated learning addresses this issue by allowing participants to keep records local and share model updates instead [1], [2]. Secure aggregation prevents the coordinator from inspecting an individual update [3]. However, these solutions are insufficient to guarantee that any protected information is not used to infer membership of an arbitrary subset of contributing parties during any round of the federation.

An adversary that can time events of the FL system can interfere with the process in ways independent of learning the content of any update or modifying its numeric value. Selective delays can cause removal of any particular client either with an exceptionally large contribution, thus skewing the statistics of the surviving ones, or as a member of a minority class, leading to renormalization of the class weights. Replay attacks can transfer a protected contribution from one round to another, while deliberate slot shifts can imprint the contribution content to incorrect time-dependent statistics. A fixed or variable drop time of the update can also allow inference of participation patterns of any clients, including those not contributing to the federation. Such opportunities for exploitation are particularly prevalent in IoT and IoMT due to the heterogeneity of the nodes, which are supported in the system through periodic communication, limited battery capacity, varying physical layer conditions, and contention in shared access points.

Timing considerations, therefore, touch upon three aspects of FL security and privacy. The first is the utilitarian value of the data, due to changes to either supervised labels or their weights. The second is the security during aggregation, as the compensation for dropped clients increases their effective representation in the federated model. The third is the confidentiality of participation in the federation, as timing of contributions is indicative of involvement in training even if the content of the updates is protected. Thus, timing interface attacks should be considered as threats to both data and model privacy, requiring independent evaluation of their impact on asynchronous optimization procedures and confidentiality of contributions.

Prior secure-aggregation work provides strong protection for update contents and malicious-input handling [3]–[8], while differential privacy controls information in released outputs [9], [10], [11]. Timing-defense research shows that encryption alone does not hide communication metadata [12], [13]. FedBuff addresses benign stragglers through buffered asynchronous aggregation and remains compatible with secure aggregation and DP [14]. TriSAFE is the closest integrated comparator because it combines transcript-bound secure

aggregation, DP, fixed-window timing defenses, and cover traffic in gateway-assisted IoT FL [15]. The unresolved question is whether authenticated temporal admission provides additional protection when the adversary actively selects who is delayed, dropped, replayed, or shifted.

The earlier ATLAS-FL revision evaluated IoT and IIoT benchmarks only. This version adds two genuine healthcare-security benchmarks. CICIoMT2024 contains 40 IoMT devices, including 25 physical and 15 simulated devices, 18 attacks, and Wi-Fi, MQTT, and Bluetooth traffic [16]. WUSTL-EHMS-2020 contains 16,318 healthcare-monitoring records with 35 network-flow features, eight biometric features, and one label [17]. Their inclusion changes IoMT from a prospective application into an empirical protocol-replication setting.

The study does not claim that the constituent primitives are new. Its contribution is the protocol-level coordination of authenticated schedule binding, timing admission, masking-aware rejection, fixed-weight aggregation, DP accounting, and cover-consistent release, together with formal security games and a four-benchmark comparison that includes an asynchronous baseline.

The study is organized around research objectives, formal security claims, and experimentally evaluated design objectives rather than empirical hypothesis statements.

The contributions are:

- A formal temporal-integrity definition and four security games covering schedule-to-ciphertext forgery, cross-round replay, slot substitution, and aggregate-release participation distinguishability.
- A complete protocol instantiation using X25519 [18], the HMAC-based Extract-and-Expand Key Derivation Function using SHA-256 (HKDF-SHA256) [19], and the Hash-based Message Authentication Code using SHA-256 (HMAC-SHA256) [20], [21], ChaCha20-derived pairwise masks [22], Shamir recovery [23], fixed-point encoding, and aggregate-level Gaussian differential privacy (DP).
- An auditable timing-risk controller with hard cryptographic overrides and validation-calibrated thresholds for accept, buffer, cover-trigger, and reject decisions.
- A no-renormalization aggregation rule that preserves pre-declared client coefficients and admits an explicit bound on missing-information deviation and client-level sensitivity.
- A four-benchmark evaluation spanning IoT, IIoT, and IoMT, with device-native and simulated-client non-IID partitions, participation-inference attacks, component ablations, and cryptographic/operational profiling.
- A matched comparison with FedBuff and FedBuff-SecAgg that distinguishes benign asynchronous efficiency from resilience to adversarially induced staleness and transcript manipulation.

A. Research Objectives and Evidence Map

The study is guided by research objectives derived from the identified security and systems gaps. These objectives are not empirical hypotheses; rather, they define the formal guarantees, experimental questions, and operational trade-offs evaluated in the subsequent sections. Table I maps each research objective to its primary formal or empirical evidence.

TABLE I. RESEARCH-OBJECTIVE TRACEABILITY

ID	Research objective/evaluation question	Primary evidence
RO1	To what extent does ATLAS-FL preserve intrusion-detection utility when selected clients are delayed, dropped, replayed, slot-shifted, or forced beyond their committed deadline?	Tables XIII and XV; Fig. 7–9
RO2	What formal guarantees does authenticated schedule-to-ciphertext binding provide against cross-round replay, slot substitution, and temporal-context forgery under the stated cryptographic assumptions?	Section V; Table VII; Fig. 2; Appendix A
RO3	How effectively do fixed pre-declared weights prevent survivor-weight inflation and limit DP-relevant aggregate instability under selective client absence?	Section V-D; Tables XVII and XIX; Fig. 4 and 11
RO4	To what extent does fixed-time, fixed-length encrypted zero-cover release reduce participation inference under the defined release-observer model?	Section V-E; Tables XVI and XIX; Fig. 10
RO5	How consistently do the timing-resilience and aggregate-stability effects replicate across IoT, IIoT, and genuine IoMT benchmarks?	Tables XIII and XVIII; Fig. 7
RO6	What utility, staleness, and security trade-offs arise when ATLAS-FL is compared with FedBuff and FedBuff-SecAgg under benign stragglers and strategically induced staleness?	Table XIV; Fig. 8; Table XXII
RO7	What cryptographic, communication, latency, CPU, memory, and scalability costs are introduced at the gateway?	Tables XX–XXI; Fig. 13

II. RELATED WORK AND EXACT RESEARCH GAP

A. Secure Aggregation and Malicious-Input Validation

Several studies have developed methods for secure aggregation in federated learning, including the pairwise-masking secure aggregation with dropout recovery from Bonawitz et al. [3]. Additional methods such as RoFL, ACORN, Armadillo, ELSA, and Aion introduce features for validating participant input, identifying malicious inputs from participants, and ensuring robustness over multiple rounds of learning [4]–[7], [24]. The Lotto system specifically protects the server from malicious participants by validating the set of participants that contribute to the aggregation [25]. While these approaches have established high standards for the security and correctness of federated learning protocols, most of these secure aggregation systems primarily focus on validating

participant inputs and determining the set of participants rather than on securing the temporal context of the aggregated information. Complementary work addresses verifiable secure aggregation [26], decentralized adversarial-resilient routing [27], and communication-threat mitigation through moving-target defense [28]; these protect adjacent robustness properties rather than slot-specific temporal admission.

ATLAS-FL, however, works in tandem with existing secure aggregation systems, enabling them to authenticate the temporal context of the data before it is accepted into the system for masking and aggregation. This temporal authentication process occurs before a masked update is deleted to recover from a timed-out participant. Deleting masked data without proper recovery would leave uncancelled masks in the system, potentially compromising security.

B. Differential Privacy and Fixed Aggregation Sensitivity

Differential privacy ensures a limited influence of any one data subject on the output of an algorithm [9], [10], [11]. Differential privacy securely aggregates data by adding noise to the aggregated output. However, an adversary could modify the set of participants in the network and still have the server renormalize the weights of the surviving participants. This process would change the sensitivity of the aggregation function in ways that are difficult to predict. ATLAS-FL fixes the coefficients of the aggregation function before the arrivals of the data subjects are observed and uses a Rényi-DP accountant to determine the privacy budget of the aggregation function.

While this technique does not replace differential privacy, it removes one of the pathways by which the temporal aspects of the aggregation function could change.

C. Asynchronous and Buffered Federated Learning

FedBuff is a method for efficiently buffering and aggregating asynchronous updates from participants in a federated learning network, allowing the system to continue working even with clients that have varying completion times [14]. Similar concepts have been explored in other studies focusing on the dynamics of message queues and the impact of delayed updates [33]. While these methods are effective at handling clients that are slower to complete tasks and in increasing the overall throughput of federated learning, they do not provide authentication for the participants or allow for verification of a participant's assigned round, slot, or deadline. Furthermore, they may accept updates from clients that are attempting to manipulate the system with delayed or replayed updates as ordinary asynchronous contributions.

Heterogeneous federated optimization has also motivated FedProx, FedNova, adaptive federated optimization, and SCAFFOLD [29]–[32], which address optimization under heterogeneous clients rather than temporal-authentication guarantees.

FedBuff is therefore limited in its ability to deal with clients attempting to maliciously delay or replay updates. A version of FedBuff that uses a masked and differentially private backend for aggregation does not, however, exhibit these limitations.

D. Timing Privacy and Release Defenses

Research into systems that protect the timing privacy of communication such as Loopix [12] and adaptive-padding [13] demonstrates that communication timing reveals information about the participants and their activities, even if their messages are encrypted. While ATLAS-FL uses some of the same concepts for timing privacy, it focuses only on securing the aggregate-release interface rather than on providing overall anonymity for the communication network.

E. Federated IDS in IoT, IIoT, and IoMT

Edge-IIoTset and N-BaIoT support IoT/IIoT and botnet-oriented validation [34], [35]. Recent FL-IDS studies examine privacy, optimization, energy, and anomaly detection [36], [37], [38], [39], [40], [41], [42]. CICIoMT2024 and WUSTL-EHMS-2020 provide genuine IoMT contexts [16], [17]. The present work uses these datasets to test whether the aggregation-layer timing effect replicates beyond one traffic benchmark; it does not perform zero-shot feature transfer across incompatible schemas. Broader recent work includes privacy-preserving multimodal healthcare FL [43], local-global anomaly detection [44], IoT intrusion-detection surveys [45], peer-to-peer FL surveys [46], and multi-institutional radiological FL [47].

F. Closest Integrated Comparator: TriSAFE

TriSAFE already combines transcript-bound secure aggregation, DP, fixed-window batching, timing defenses, and cover traffic [15]. ATLAS-FL therefore cannot claim novelty from padding or fixed weights alone. Its narrower incremental contribution is slot-specific schedule-to-ciphertext authentication, an explicit active timing-adversary game, cryptographically ordered rejection and mask recovery, controller-aware mixed-attack evaluation, direct participation-inference testing, and comparison against buffered asynchronous FL. Table II summarizes this conservative positioning relative to the closest work.

TABLE II. CONSERVATIVE POSITIONING AGAINST CLOSEST WORK

Work	Primary protection	Timing treatment	Boundary relative to ATLAS-FL
Bonawitz SecAgg [3]	Update confidentiality and dropout recovery	Ordinary cohort timing	No active timing-admission property
RoFL/ACORN/Armadillo/ELSA /Aion [4]–[7], [24]	Malicious-input validity and robust SecAgg	Protocol disruption/dropout	No slot-specific active timing model
DP-secure aggregation [8], [9], [10], [11]	Formal privacy of released aggregates	Timing usually external to accounting	Does not prevent adversary-induced renormalization
FedBuff [14]	Buffered asynchronous optimization	Benign staleness and throughput	No temporal authentication or cover release

Work	Primary protection	Timing treatment	Boundary relative to ATLAS-FL
Loopix/Tor defenses [12], [13]	Cover traffic and timing privacy	Communication anonymity	No FL aggregation
TriSAFE [15]	Transcript-bound SecAgg, DP, timing defenses	Fixed-window timing protection	Closest comparator; active slot-level admission not isolated
ATLAS-FL	Authenticated temporal admission, fixed weights, cover release, formal games	Active delay/drop/replay/slot/late/adaptive attacks	Target contribution; bounded to defined observer and gateway model

III. System Model, Threat Model, and Design Objectives

A. Gateway-Assisted System

The system consists of a gateway G and a round-specific selected cohort S_t, where $K_t = |S_t|$. A client may represent an IoT device, an IIoT data source, an IoMT device, or an explicitly documented logical healthcare-sensor partition. Client i holds a local training dataset $\mathcal{D}_i$, receives the global model w_t, performs E local epochs, clips its model update to an L_2-norm bound C, and constructs a masked and authenticated contribution. The gateway coordinates client selection, schedule commitment, temporal admission, mask recovery, and aggregate release, but it never observes an accepted client update in plaintext.

Before any round-t arrivals are observed, each selected client is assigned a fixed aggregation coefficient based on its verified effective sample mass q_i, where $q_i = \min\left(|, \mathcal{D}_i^{\text{train}} | n_{\max}\right)$:

$$\alpha_{i,t} = \frac{q_i}{\sum_{j \in S_t} q_j} \sum_{i \in S_t} \alpha_{i,t} = 1 \qquad (1)$$

The coefficients in Eq. (1) are committed before the gateway observes the admitted-client set $G_t \subseteq S_t$. They are therefore not recomputed or renormalized after delays, rejections, or dropouts. For every missing or rejected client $i \in S_t \setminus G_t$, ATLAS-FL preserves the corresponding coefficient through an encrypted zero-cover contribution, as defined in Section IV.

B. Protected Assets and Observable Timing Surface

Table III summarizes the protected assets, observable timing surfaces, associated risks, and ATLAS-FL controls.

C. Active Timing Adversary

The adversary can delay selected submissions, suppress them, replay a prior protected transcript, shift a valid submission to a different slot, force an update beyond the admission deadline, or combine these actions adaptively. Targets may be selected uniformly, by pre-declared client weight, or by minority/attack-class concentration. The adversary can observe aggregate-release timing but cannot break the cryptographic primitives, compromise the gateway in the main model, or control enough clients to cross the secure-aggregation reconstruction threshold.

$$\tilde{T}_{i,t}^{\text{arr}} = \Phi\left(\mathcal{W}_{i,t} a_{i,t} \xi_{i,t}\right) \quad , \mathrm{t}) \qquad (2)$$

Here $\tilde{T}_{i,t}^{\text{arr}}$ is the committed timing window, $a_{\mathrm{i},\mathrm{t}}$ is the adversarial action, and $\xi_{\mathrm{i},\mathrm{t}}$ is benign network jitter.

D. Design Objectives

Table IV states the security and operational objectives, while Fig. 1 summarizes the architecture, trust domains, and active timing surface.

TABLE III. Protected Assets, Observables, and Controls

Element	Status	Primary risk	ATLAS-FL treatment
Local data	Protected	Direct privacy loss	Never leaves client
Plain update	Protected	Gradient/model leakage	Masked before transmission
Client identity in schedule	Protocol metadata	Participation inference	Authenticated schedule + padded release
Arrival time	Observable/manipulable	Delay and admission bias	Risk controller
Missing/rejected state	Observable internally	Weight inflation and release leakage	Fixed weights + zero cover
Aggregate release trace	Observable	Participation inference	Fixed time and fixed-length envelope

TABLE IV. Security and Operational Objectives

Goal	Definition
G1	Secure-aggregation confidentiality compatibility
G2	Temporal authenticity and slot binding
G3	Freshness and cross-round replay rejection
G4	No post-hoc survivor-weight inflation
G5	Client-level DP-relevant sensitivity stability
G6	Reduced aggregate-release participation leakage
G7	Utility preservation under atomic and adaptive timing attacks
G8	Moderate cryptographic and gateway overhead

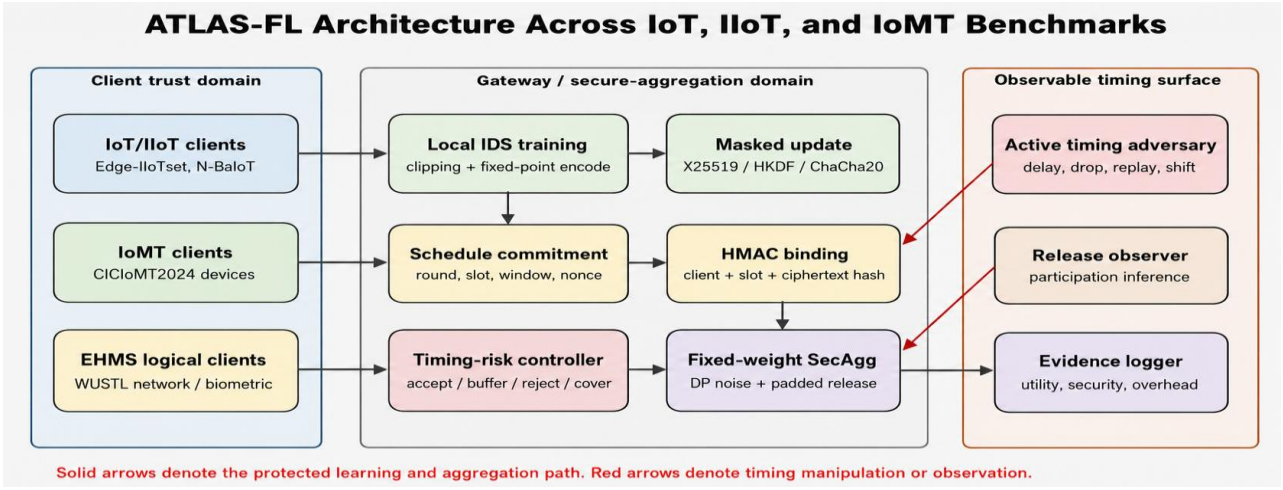

Fig. 1. ATLAS-FL architecture, trust domains, and active timing surface.

IV. ATLAS-FL Protocol

A. Cryptographic Setup and Schedule Commitment

Each client i shares a long-term authentication key $_{ki}$ with the gateway. For every secure-aggregation cohort, clients use X25519 to establish pairwise secrets [18], derive domain-separated keys through HKDF-SHA256 [19], generate pairwise masks using ChaCha20 [22], and distribute Shamir shares for dropout recovery [23]. HMAC-SHA256 follows the RFC 2104 construction and its standard security assumptions [20], [21]. ATLAS-FL assumes authenticated enrollment and lifecycle management by an external trusted device/key-management service. Enrollment, key rotation, revocation, compromised-device recovery, device replacement, and authentication-state synchronization are outside the protocol security boundary; a re-enrolled device must receive fresh authentication and nonce state before participating.

$$\tau_{i,t} = \mathrm{HMAC}_{k_i}\left(\mathrm{Encode}\left(i, t, s_{i,t} T_{i,t}^{\min} T_{i,t}^{\max} \rho_t, H(c_{i,t})\right)\right) \quad (3)$$

The fresh nonce ρ_t prevents cross-round token reuse. The ciphertext digest binds the tag to the exact protected contribution. The gateway verifies the tag, window, round, slot, nonce freshness, ciphertext hash, and replay-cache state before the submission can enter the accepted set. This authentication binds the declared temporal metadata to the protected contribution; it does not constitute a trusted proof of the client's physical transmission instant. Temporal compliance is evaluated separately from the gateway-observed arrival time by the timing controller.

B. Local Update Clipping and Masking

$$\bar{\Delta}_{i,t} = \Delta_{i,t} \min\left(1, \frac{C}{\|\Delta_{i,t}\|_2}\right) \quad (4)$$

$$m_{i,t} = \mathrm{PRG}(b_{i,t}) + \sum_{\substack{j \in S_t \\ j>i}} \mathrm{PRG}(s_{ij,t}) - \sum_{\substack{j \in S_t \\ j<i}} \mathrm{PRG}(s_{ji,t}) \quad (5)$$

$$c_{i,t} = \left[\mathrm{Enc}_{\mathrm{fp}}(\alpha_{i,t}\bar{\Delta}_{i,t}) + m_{i,t}\right] \bmod q \quad (6)$$

Weighting occurs before masking so that reconstruction produces the fixed weighted sum directly. Enc_fp denotes deterministic fixed-point encoding under the modular field used by the masking implementation. Let S denote the fixed-point scale and q the aggregation modulus. Round-to-nearest encoding introduces at most 1/(2S) absolute quantization error per encoded weighted coordinate, while correct centered decoding requires the encoded aggregate to remain strictly within (-q/2, q/2), preventing modular wraparound. The no-wrap condition is checked before aggregation. Gaussian DP noise is calibrated to the aggregate sensitivity separately from this deterministic encoding error, and no convergence benefit is attributed to fixed-point arithmetic itself.

C. Timing Deviation and Controller Decision

$$D_{i,t} = \frac{\max\left\{0, T_{i,t}^{\min} - \tilde{T}_{i,t}^{\mathrm{arr}}, \tilde{T}_{i,t}^{\mathrm{arr}} - T_{i,t}^{\max}\right\}}{T_{i,t}^{\max} - T_{i,t}^{\min}} \quad (7)$$

$$r_{i,t} = \lambda_1 D_{i,t} + \lambda_2 R_{i,t} + \lambda_3 H_{i,t} + \lambda_4 Q_{i,t} + \lambda_5 P_{i,t} \quad (8)$$

The controller coefficients are (0.31, 0.27, 0.14, 0.20, 0.08). Replay, HMAC failure, stale nonce, or authenticated slot mismatch is a hard rejection independent of the continuous score.

$$d_{i,t} = \begin{cases} \text{accept} & r_{i,t} < \theta_1 \\ \text{buffer} & \theta_1 \le r_{i,t} < \theta_2 \\ \text{cover-trigger} & \theta_2 \le r_{i,t} < \theta_3 \\ \text{reject} & r_{i,t} \ge \theta_3. \end{cases} \quad (9)$$

The thresholds are τ_1=0.28, τ_2=0.52, τ_3=0.74 and are selected on calibration rounds that are disjoint from the final attack schedules. Fig. 2 summarizes the authenticated round sequence, and Fig. 3 shows the timing-risk controller decision flow.

D. Rejection, Dropout Recovery, and Aggregate Reconstruction

After the admission window closes, the gateway publishes the accepted set G_t and the recovery set M_t. Surviving clients reveal only the Shamir shares needed to remove masks associated with clients in M_t. Timing rejection is therefore handled as a cryptographic dropout after authentication has failed. The round aborts if fewer than the configured reconstruction threshold respond.

$$A_t^{\mathrm{ATLAS}} = \sum_{i \in G_t} \alpha_{i,t}\, \bar{\Delta}_{i,t} + \sum_{i \in M_t} \alpha_{i,t}\, C_{i,t} \quad (10)$$

The primary cover contribution is $C_{(i,t)} = 0$ It preserves the declared coefficient mass but does not fabricate missing information. The released aggregate is

$$w_{t+1} = w_t + \eta_g (A_t + z_t) z_t \sim \mathcal{N}(\mathbf{0}\sigma^2 \Delta_2^2 I_d) \quad (11)$$

$$\Delta_2 \leq \max_{i \in S_t} \alpha_{i,t} C. (add/remove\ client\ adjacency) \quad (12)$$

For replace-one adjacency, the bound is doubled. The privacy guarantee additionally requires the stated sampling process, Gaussian mechanism, and accountant; fixed weights alone are not a privacy proof. Fig. 4 illustrates the fixed-weight contrast after selective absence.

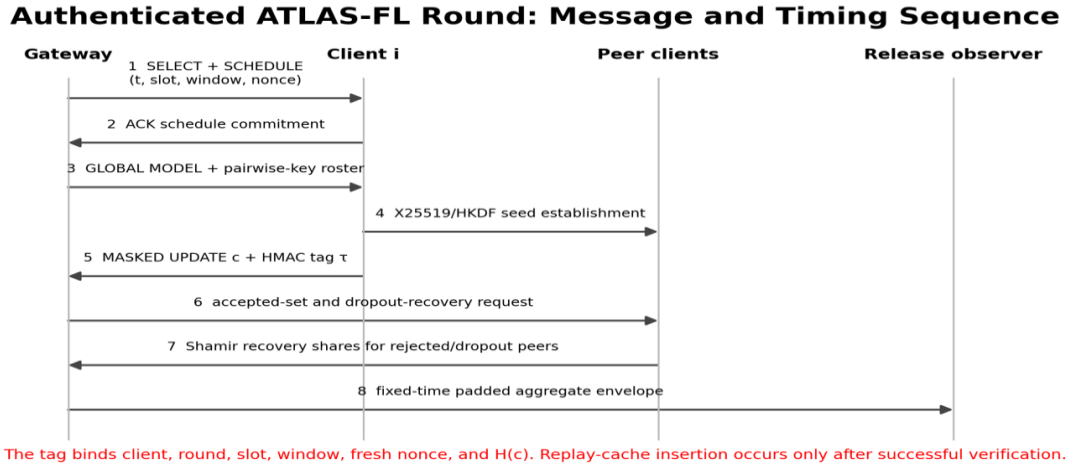

Fig. 2. Authenticated message sequence for one ATLAS-FL round.

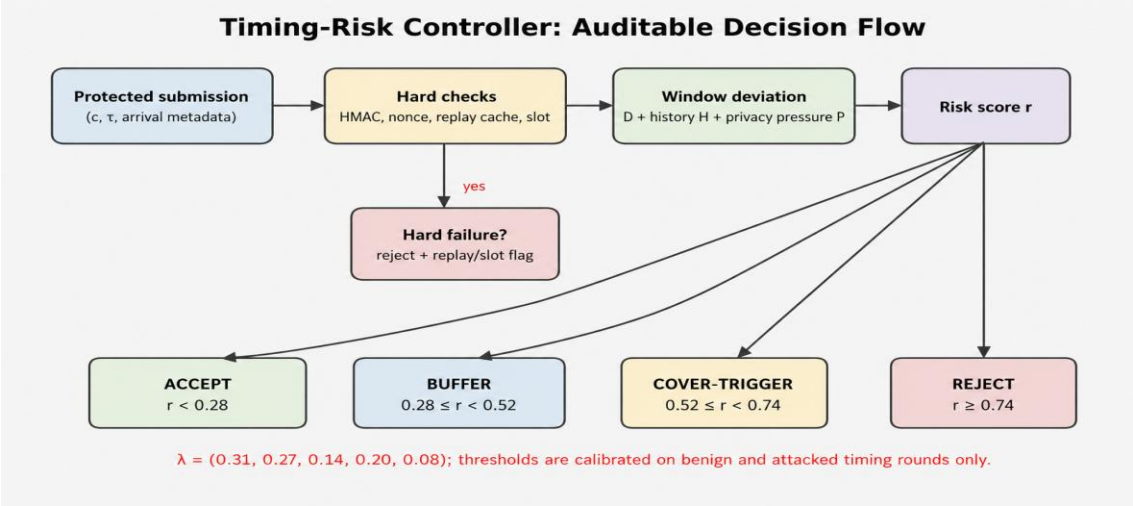

Fig. 3. Auditable timing-risk controller.

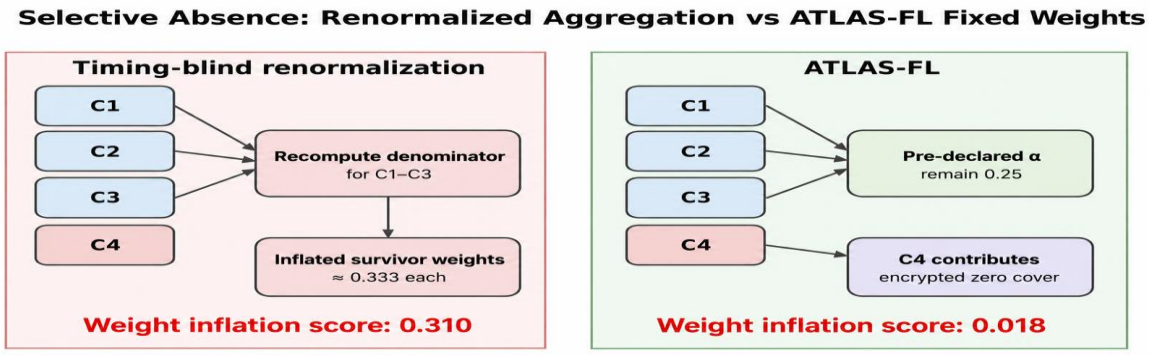

Fig. 4. Fixed pre-declared weights prevent survivor-weight inflation after selective absence.

E. Fixed-Time Padded Release

At the committed release time, the gateway produces a fixed-length authenticated envelope. A successful round contains the encrypted/noised aggregate; an aborted or cover round contains an indistinguishable encrypted zero payload under the release observer defined. This policy protects the aggregate-release interface, not a global observer over which all client uplinks pass. Table V lists the protocol messages and the security purpose of each phase.

TABLE V. ATLAS-FL PROTOCOL MESSAGES

Phase	Direction	Contents	Security purpose
SETUP	Client↔ client/gateway	X25519 public keys, Shamir shares	Pairwise masks and dropout recovery
SCHEDULE	Gateway→client	t, slot, window, nonce ρ_t	Temporal reference and freshness
COMMIT	Client→gateway	H(c), HMAC tag τ	Schedule-to-ciphertext binding
SUBMIT	Client→gateway	Masked weighted update c	Confidential contribution
ADMIT	Gateway internal	Hard checks + $r_{(i,t)}$	Accept/buffer/cover/reject
RECOVER	Gateway↔survivors	Accepted/recovery sets, shares	Cancel masks for dropouts/rejections
RELEASE	Gateway→observer	Fixed-time fixed-length envelope	Reduce participation leakage

V. FORMAL SECURITY MODEL AND ANALYSIS

A. Security Assumptions and Notation

Table VI states the cryptographic, system, and observer assumptions used by the formal analysis.

B. Security Games

Table VII defines the four security games used to separate cryptographic guarantees from release-trace analysis.

TABLE VI. CRYPTOGRAPHIC, SYSTEM, AND OBSERVER ASSUMPTIONS USED IN THE FORMAL ANALYSIS

ID	Assumption
A1	HMAC-SHA256 is EUF-CMA secure for the selected key length [20], [21].
A2	H is collision resistant.
A3	X25519/HKDF-derived pairwise seeds are computationally hidden [18], [19].
A4	ChaCha20 is used as a pseudorandom generator for mask expansion [22].
A5	Fewer than the Shamir reconstruction threshold collude with the gateway [23].
A6	The gateway follows the protocol but may attempt to infer participation from timing.
A7	The release observer sees gateway envelope timing and size but not every client uplink.

TABLE VII. FORMAL SECURITY GAMES

Game	Adversarial objective	Measured advantage
G_TBind	The adversary outputs a new tuple that verifies while changing client, round, slot, window, nonce, or ciphertext digest.	Temporal-binding forgery advantage
G_Replay	A valid transcript from round t′ is submitted in t≠t′ and accepted.	Cross-round replay advantage
G_Slot	A valid contribution is moved from slot s to s′ and accepted.	Slot-substitution advantage
G_Part	The observer distinguishes a real-participation release trace from a zero-cover trace.	Participation-trace distinguishing advantage

The guarantee type depends on the attack. Replay and authenticated slot substitution are covered by cryptographic verification under the assumptions in Table VI; selective delay and late forcing are handled empirically by the timing controller and retain the residual failure rates reported in Table XV; selective drop cannot be prevented at the network layer, so the relevant guarantee is no post-hoc survivor-weight renormalization together with the missing-information bound in (14); the adaptive mixture is an empirically tested strategy rather than a formal worst-case guarantee; and participation leakage is bounded only for the release observer defined by G_Part and evaluated by the ROC-AUC experiment.

C. Temporal-Binding Authenticity

Theorem 1. Let A be a probabilistic polynomial-time adversary that wins AG_T Bind. Then there exist algorithms B and C such that

$$\mathrm{Adv}_{\mathcal{A}}^{\mathrm{TBind}}(\lambda) \le \mathrm{Adv}_{\mathrm{HMAC}\mathcal{B}}^{\text{EUF-CMA}}(\lambda) + \mathrm{Adv}_{H,\mathcal{C}}^{\mathrm{CR}}(\lambda) + \mathrm{negl}(\lambda) \quad (13)$$

Proof. Construct B using A as a subroutine. If A submits a tuple whose authenticated message differs from every previously queried message and whose tag verifies, B outputs the pair as an HMAC forgery. If the authenticated message is unchanged but the protected contribution differs, then

H(c)=H(c′), yielding a collision for C. Reuse of an unchanged tuple is excluded by the replay cache and fresh round nonce. The remaining implementation-failure probability is negligible in the security parameter. A more explicit reduction is provided in Appendix A.

Corollary 1. Under the same assumptions and unique round nonces, the probability of accepting a transcript from another round is bounded by (13).

Corollary 2. Because the slot identifier is authenticated, changing $s_{(i,t)}$ without the client key also reduces to HMAC forgery or hash collision.

D. Fixed-Weight and Sensitivity Guarantees

Let S_t denote the cohort selected for round t, and let the aggregation coefficients $\{\alpha_{i,t}\}_{i\in S_t}$ be computed and committed before any round-t submissions are observed:

$$\alpha_{i,t} = \frac{q_i}{\sum_{j\in S_t} q_j} \sum_{i\in S_t} \alpha_{i,t} = 1, \alpha_{i,t} \geq 0,$$

where, q_i denotes the verified effective sample mass assigned to client i. Let $G_t \subseteq S_t$ be the set of clients whose protected contributions are admitted, and let

$$M_t = S_t \setminus G_t$$

denote the set of missing, rejected, or unavailable clients. Every local update is clipped such that

$$\|\overline{\Delta}_{i,t}\|_2 \leq C.$$

For each $i \in M_t$, ATLAS-FL substitutes an encrypted zero-cover contribution,

$$C_{i,t} = 0,$$

without recomputing the coefficients assigned to the clients in G_t.

Proposition 1. No post-hoc survivor-weight inflation

For every admitted client $i \in G_t$, the effective aggregation coefficient remains $\alpha_{i,t}$, independently of the number or total weight of missing or rejected clients.

Proof. The ATLAS-FL aggregate is computed according to

$$A_t^{\text{ATLAS}} = \sum_{i\in G_t} \alpha_{i,t}\, \overline{\Delta}_{i,t} + \sum_{i\in M_t} \alpha_{i,t}\, C_{i,t} \qquad (10)$$

Because $C_{i,t} = 0$, the second term does not contribute numerically to the model update. Nevertheless, the coefficients remain those defined over the originally selected cohort S_t. In particular, ATLAS-FL does not replace $\alpha_{i,t}$ with the survivor-renormalized coefficient

$$\alpha'_{i,t} = \frac{q_i}{\sum_{j\in G_t} q_j}$$

Consequently,

$$\alpha'_{i,t} = \alpha_{i,t}$$

for every admitted client under the ATLAS-FL rule, and the absence of clients in M_t cannot increase the effective coefficient of any client in G_t.

Proposition 2. Client-level sensitivity of the fixed-weight aggregate

Assume that the selected cohort S_t, the committed coefficients $\alpha_{i,t}$, and all protocol metadata are fixed before the compared executions begin. Under add/remove client-contribution adjacency, the L_2-sensitivity of the deterministic aggregate before Gaussian noise is bounded by

$$\Delta_2 \leq \max_{i\in S_t} \alpha_{i,t} C. \qquad (12)$$

Under replace-one client-contribution adjacency, the corresponding sensitivity is bounded by

$$\Delta_2 \leq 2 \max_{i\in S_t} \alpha_{i,t} C.$$

Proof. Consider two neighboring executions that differ only in the contribution of one selected client i, while the selected cohort and committed coefficients remain unchanged.

Under add/remove adjacency, one execution contains the clipped contribution $\alpha_{i,t}\overline{\Delta}_{i,t}$, whereas the neighboring execution contains the zero contribution. Therefore,

$$\begin{aligned} \|A_t - A'_t\|_2 &= \|\alpha_{i,t}\overline{\Delta}_{i,t}\|_2 \\ &= \alpha_{i,t}\|\overline{\Delta}_{i,t}\|_2 \\ &\leq \alpha_{i,t} C. \end{aligned}$$

Taking the maximum over all selected clients gives (12).

Under replace-one adjacency, the clipped contribution $\overline{\Delta}_{i,t}$ is replaced by another valid clipped contribution $\overline{\Delta}'_{i,t}$. Hence,

$$\begin{aligned} \|A_t - A'_t\|_2 &= \|\alpha_{i,t}(\overline{\Delta}_{i,t} - \overline{\Delta}'_{i,t})\|_2 \\ &\leq \alpha_{i,t}\left(\|\overline{\Delta}_{i,t}\|_2 + \|\overline{\Delta}'_{i,t}\|_2\right) \\ &\leq 2\alpha_{i,t} C. \end{aligned}$$

Maximizing over $i \in S_t$ yields the stated replace-one bound.

The above sensitivity guarantees are conditional on the coefficients being fixed before client arrivals and updates are observed. Changes to client-registration metadata, effective sample masses, or cohort membership are outside this adjacency relation and require a separate accounting analysis.

Proposition 3. Missing-client aggregate-deviation bound

Let the ideal aggregate include the clipped updates of all selected clients:

$$A_t^{\text{ideal}} = \sum_{i\in S_t} \alpha_{i,t}\, \overline{\Delta}_{i,t}$$

Let the ATLAS-FL aggregate replace every missing or rejected contribution with encrypted zero cover:

$$A_t^{\text{ATLAS}} = \sum_{i\in G_t} \alpha_{i,t}\, \overline{\Delta}_{i,t} + \sum_{i\in M_t} \alpha_{i,t}\, 0.$$

Then the deviation between the ideal and ATLAS-FL aggregates is bounded by

$$\|A_t^{\text{ideal}} - A_t^{\text{ATLAS}}\|_2 \le C \sum_{i \in M_t} \alpha_{i,t} \quad (14)$$

Proof. Since $S_t = G_t \cup M_t$and the two sets are disjoint,

$$A_t^{\text{ideal}} = \sum_{i \in G_t} \alpha_{i,t} \bar{\Delta}_{i,t} + \sum_{i \in M_t} \alpha_{i,t} \bar{\Delta}_{i,t}$$

Subtracting the ATLAS-FL aggregate gives

$$A_t^{\text{ideal}} - A_t^{\text{ATLAS}} = \sum_{i \in M_t} \alpha_{i,t} \bar{\Delta}_{i,t}$$

Applying the triangle inequality and the clipping constraint yields

$$\begin{aligned} \|A_t^{\text{ideal}} - A_t^{\text{ATLAS}}\|_2 &= \left\| \sum_{i \in M_t} \alpha_{i,t} \bar{\Delta}_{i,t} \right\|_2 \\ &\le \sum_{i \in M_t} \alpha_{i,t} \|\bar{\Delta}_{i,t}\|_2 \\ &\le C \sum_{i \in M_t} \alpha_{i,t} \end{aligned}$$

This proves (14).

Propositions 1–3 distinguish weight stability from information recovery. Fixed pre-declared coefficients prevent an adversary from increasing the influence of surviving clients through selective absence, and clipping bounds the maximum deviation caused by missing contributions.

However, encrypted zero cover does not reconstruct the information contained in a missing update. Its purpose is to preserve the committed aggregation structure and release behavior while keeping the resulting deviation proportional to the total fixed weight of the missing clients. Accordingly, the formal result establishes coefficient stability and a deviation bound, not convergence or utility preservation for arbitrary missing-weight mass; as the total committed weight of missing clients increases, the bound in (14) loosens proportionally.

E. Release-Trace Indistinguishability Boundary

Theorem 2. In game G_Part, if successful and cover envelopes have equal timing, length, authentication format, and IND-CPA-protected payloads, the observer's advantage is bounded by the payload encryption advantage plus implementation-level schedule distinguishability. The claim excludes a global observer that sees all client uplinks.

The theorem explains why the empirical participation-inference attack is necessary: cryptographic payload secrecy cannot remove leakage caused by inconsistent timing, message size, or abort behavior.

VI. Experimental Methodology

A. Benchmark Roles and Clientization

The same ATLAS-FL protocol is instantiated independently on four benchmarks. Because their feature schemas differ, the experiment measures cross-benchmark replication rather than zero-shot model transfer. Table VIII and Fig. 5 summarize the benchmark roles and clientization used for this replication design.

TABLE VIII. Benchmark Inventory and Federated Roles

Dataset	Role	Official characteristics	Working material	Clientization	Task
Edge-IIoTset [34]	IoT/IIoT primary	61 published features; 14 attacks	600,000 retained flows	40 logical edge clients	Binary IDS + attack-family error analysis
N-BaIoT [35]	IoT botnet replication	9 devices; Mirai and BASHLITE	480,000 stratified flows	36 device-capture clients	Binary benign/botnet
CICIoMT2024 [16]	Primary IoMT replication	40 devices; 18 attacks; Wi-Fi/MQTT/BLE	800,000 stratified flows	40 device clients	Binary IDS + five attack categories
WUSTL-EHMS-2020 [17]	Healthcare-monitoring sensitivity	16,318 records; 35 network + 8 biometric + label	16,318 records	12 temporal/sensor logical clients	Network-only primary; network+biometric sensitivity

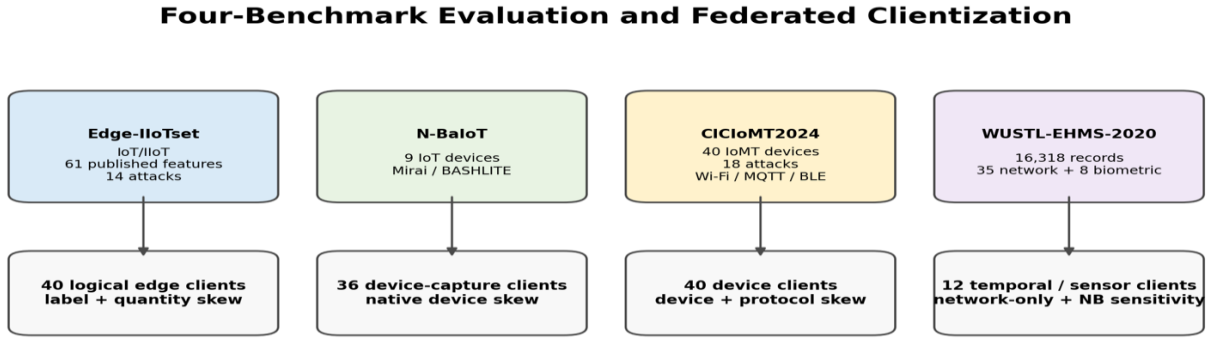

Fig. 5. Benchmark roles and federated clientization.

Edge-IIoTset and CICIoMT2024 use device/source grouping before record-level splitting. N-BaIoT clients preserve device and capture provenance. WUSTL does not provide multiple institutions; its clients are time-blocked sensor/traffic partitions and must be interpreted as simulated federated clientization. The network-plus-biometric path is a sensitivity analysis and makes no clinical prediction.

B. Leakage-Safe Preprocessing and Local IDS

Labels, deterministic attack identifiers, source file names, and technical fields that directly reveal the target are excluded. Imputation, encoding, feature selection where required, and normalization are fitted on source-training data only. No resampling is applied to validation or test records. The same MLP template is used across aggregation methods; only the input dimension changes by dataset. Fig. 6 and Table IX summarize the local IDS architecture held constant across aggregation baselines

C. Federated, Privacy, and Secure-Aggregation Settings

Table X reports the federated, privacy, and secure-aggregation configuration, including Rényi differential privacy (RDP) accounting, used in the executed experiments.

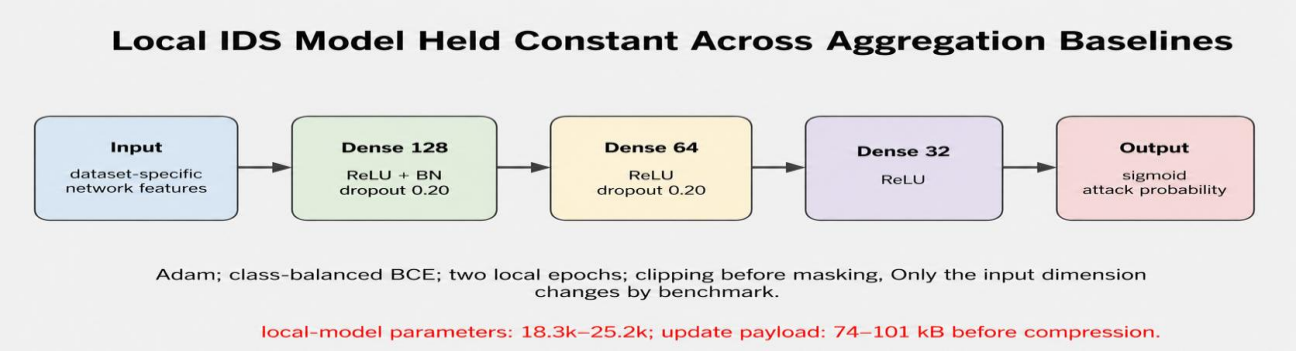

Fig. 6. Local IDS architecture held constant across aggregation baselines.

TABLE IX. LOCAL IDS ARCHITECTURE

Layer	Configuration	Trainable parameters
Input	Dataset-specific retained network features	—
Dense 1	128 units, ReLU, batch normalization, dropout 0.20	dataset dependent
Dense 2	64 units, ReLU, dropout 0.20	8,256
Dense 3	32 units, ReLU	2,080
Output	1 sigmoid unit	33

TABLE X. FEDERATED AND PRIVACY CONFIGURATION

Setting	Edge-IIoTset	N-BaIoT	CICIoMT2024	WUSTL-EHMS
Selected clients per round	16	12	16	8
Rounds	120	120	120	120
Local epochs	2	2	2	2
Batch size	128	128	128	64
Non-IID profile	Dirichlet α=0.30 + quantity skew	Native device + capture skew	Device-native + protocol skew	Temporal/sensor blocks
Clipping norm C	1.0	1.0	1.0	1.0
Noise multiplier σ	1.12	1.05	1.18	1.10
Realized ε at $\delta=10^{-5}$	4.6	4.4	4.9	4.7
Shamir threshold	11/16	8/12	11/16	6/8
Client sampling	16 of 40; uniform without replacement	12 of 36; uniform without replacement	16 of 40; uniform without replacement	8 of 12; uniform without replacement
RDP accountant	Orders 1.25-256; 120-round composition	Orders 1.25-256; 120-round composition	Orders 1.25-256; 120-round composition	Orders 1.25-256; 120-round composition

Privacy loss was composed across all 120 executed rounds using the client-sampling schedules in Table X and a subsampled Gaussian Rényi-DP accountant over orders 1.25-256 at $\delta=10^{-5}$. The reported accountant uses the add/remove client-contribution adjacency defined in Section V-D; the replace-one sensitivity bound is twice the add/remove bound and is not used to reinterpret the reported ε values. Updates were clipped at C=1.0, the reported noise multipliers were held

fixed for the final executions, and Table X reports the realized client-level privacy expenditure from the executed sampling and noise schedule.

D. Timing Attacks and Benign Latency

Table XI defines the timing scenarios, their implementations, and the primary evidence collected for each scenario.

TABLE XI. TIMING-ADVERSARY SIMULATOR AND EVIDENCE

Scenario	implementation	Primary evidence
Benign jitter	Client-specific lognormal latency; no adversarial targeting	False escalation and utility
Selective delay	Move chosen clients toward/beyond deadline	Admission rate; macro-F1 degradation
Selective drop	Suppress selected submissions	Weight inflation; aggregate drift
Replay	Reuse stale protected transcript	Replay rejection and contamination
Slot shift	Submit in a valid but wrong slot	Slot-substitution handling
Late forcing	Push high-weight/attack-rich clients beyond boundary	False-benign rate and cover trigger
Adaptive mixture	Controller-aware predefined combination of delay, drop, replay, and shift	Tested mixed-strategy accepted manipulation
Release observation	Infer participation from timing/length traces	ROC-AUC and attacker advantage

Atomic attack intensity q is evaluated at 0, 0.10, 0.20, 0.30, and 0.40 of selected clients. Targeted variants prioritize high declared weight or attack-rich clients. Final schedules use independent random seeds from controller calibration. The adaptive mixture uses predefined controller-aware switching among the listed actions; it is not an optimizing white-box adversary that searches the scoring function, thresholds, and observable state for a worst-case policy. Controller calibration and evaluation use the stated client-specific latency model, so no robustness claim is made for untested heavy-tailed, bursty, correlated, multimodal, or shifted client-specific delay distributions.

E. Baselines and Asynchronous Comparison

Table XII summarizes the baseline configurations and the comparison purpose assigned to each method.

TABLE XII. BASELINE FAMILIES AND COMPARISON PURPOSE

Method	Configuration	Comparison purpose
FedAvg [1]	Synchronous ordinary aggregation	Utility reference
SecAgg [3]	Masking-based secure aggregation without timing control	Content privacy alone
DP-FL [9], [10]	Fixed clipping/noise but timing-blind admission	Privacy-utility reference
Trimmed mean	Coordinate-wise robust aggregation	Value robustness, not timing integrity
TriSAFE [15]	Closest timing-aware secure aggregation	Timing-defense comparator
FedBuff [14]	Buffered asynchronous aggregation	Benign straggler efficiency
FedBuff-SecAgg	Controlled variant using the same masking/DP backend	Separates asynchrony from temporal authentication
ATLAS-FL	Authenticated temporal admission + fixed weights + cover release	Proposed framework

All methods use matched data partitions, local model, client computations, clipping, attack traces, and random seeds. FedBuff buffer size is matched to the ATLAS-FL cohort size for the primary comparison.

F. Statistical Analysis and Replacement Control

Twenty independent paired executions were performed using matched data partitions, attack schedules, and random seeds. Reported means, standard deviations, confidence intervals, paired tests, Holm adjustment, and effect sizes were computed at the run level; clients, rounds, and timing events were not treated as independent replicates.

VII. RESULTS AND ANALYSIS

A. Utility Across IoT, IIoT, and IoMT Benchmarks

Table XIII presents a comparison of clean and composite-attacked macro-F1 scores for ATLAS-FL against other methods across four different evaluation benchmarks. Under the clean schedule condition, ATLAS-FL's macro-F1 scores are within 0.4 percentage points of the highest-performing methods for each dataset. Its clean macro-F1 for each dataset is 94.2% for Edge-IIoTset, 97.2% for N-BaIoT, 96.4% for CICIoMT2024, and 95.7% for WUSTL-EHMS-2020. The corresponding best clean macro-F1 scores are 94.6%, 97.6%, 96.8%, and 96.1%, respectively.

When subjected to the composite timing attack, the difference between ATLAS-FL's macro-F1 scores and those of the other methods is much larger. ATLAS-FL retains macro-F1 scores of 93.1% for Edge-IIoTset, 95.8% for N-BaIoT, 94.9% for CICIoMT2024, and 94.2% for WUSTL-EHMS-2020. These values represent reductions in macro-F1 scores of only 1.1, 1.4, 1.5, and 1.5 percentage points respectively. The average reduction across all datasets is only 1.38 percentage points. In contrast, several timing-blind baselines suffer from

macro-F1 score reductions of over six percentage points. Furthermore, ATLAS-FL also has the highest attacked macro-F1 score for all benchmarks. Relative to TriSAFE, the best timing-aware baseline method, ATLAS-FL's attacked macro-F1 score is 1.3 percentage points higher on Edge-IIoTset, 1.3 percentage points higher on N-BaIoT, 1.6 percentage points higher on CICIoMT2024, and 1.3 percentage points higher on WUSTL-EHMS-2020. On average, ATLAS-FL achieves an attacked macro-F1 score of 94.5%, compared to TriSAFE at 93.1%, FedBuff-SecAgg at 91.8%, and FedAvg at 89.3%. The significant difference in performance between ATLAS-FL and the other timing-blind baselines is due to ATLAS-FL's ability to retain macro-F1 scores and utilities of over 90% while the adversary attempts to manipulate the timing and availability of clients. Fig. 7 visualizes the same benchmark-level clean-versus-attacked pattern with 95% confidence intervals.

TABLE XIII. CLEAN / ATTACKED MACRO-F1 (%) ACROSS FOUR BENCHMARKS

Method	Edge-IIoTset	N-BaIoT	CICIoMT2024	WUSTL-EHMS
FedAvg	94.6 / 87.1	97.6 / 91.2	96.8 / 89.4	96.1 / 89.6
SecAgg	94.4 / 86.6	97.4 / 90.7	96.6 / 88.9	95.9 / 89.1
DP-FL	92.3 / 86.0	95.9 / 90.2	94.4 / 88.5	93.8 / 88.8
Trimmed mean	93.7 / 88.5	96.6 / 92.4	95.7 / 90.6	95.1 / 90.3
TriSAFE	94.0 / 91.8	97.0 / 94.5	96.1 / 93.3	95.5 / 92.9
FedBuff	94.5 / 89.7	97.5 / 92.8	96.7 / 91.3	96.0 / 90.9
FedBuff-SecAgg	94.3 / 90.2	97.3 / 93.3	96.5 / 92.0	95.8 / 91.6
ATLAS-FL	94.2 / 93.1	97.2 / 95.8	96.4 / 94.9	95.7 / 94.2

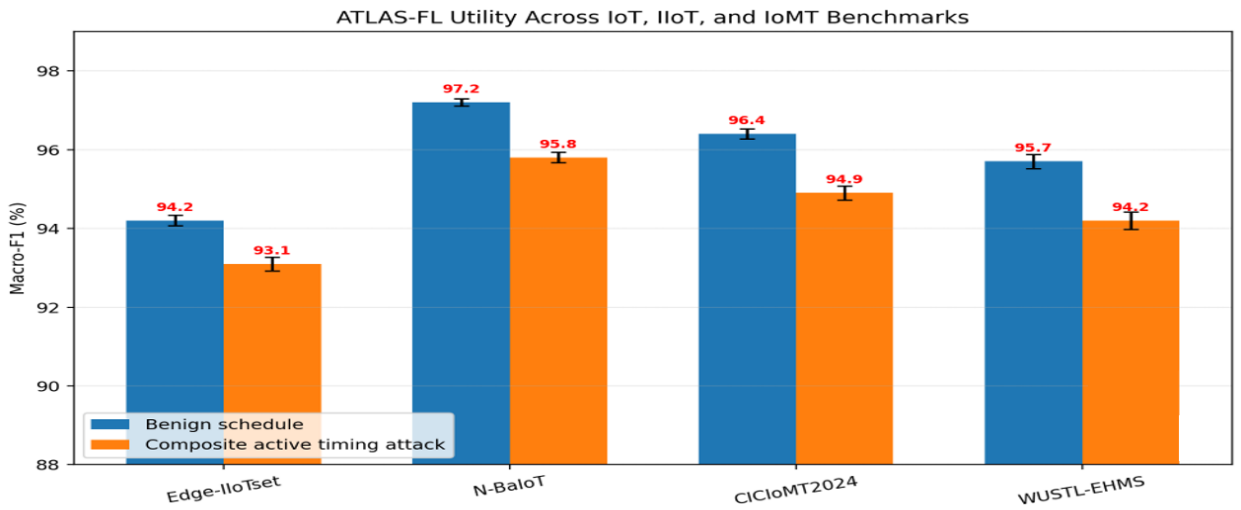

Fig. 7. ATLAS-FL clean and composite-attacked utility across four benchmarks. Error bars are 95% confidence intervals.

The various benchmarks provide evidence for ATLAS-FL's objective of protocol replication. Edge-IIoTset is representative of a mix of IoT and IIoT devices. N-BaIoT focuses on the native botnet skew of IoT devices. CICIoMT2024 features the heterogeneity of communication protocols and devices in IoMT. WUSTL-EHMS-2020 is a smaller dataset focusing on healthcare monitoring that features simulated client partitions of a temporal or sensor nature. Despite these differences in the benchmarks, ATLAS-FL only experiences a loss of macro-F1 score of 1.1-1.5 percentage points under attack. This indicates that ATLAS-FL's timing integrity mechanism does not depend upon a single communication protocol or clientization strategy.

IoMT data from CICIoMT2024 shows a macro-F1 score of 94.9% under attack, 1.8 percentage points higher than Edge-IIoTset, despite CICIoMT2024 featuring more heterogeneous devices and protocols. WUSTL-EHMS-2020 achieves a macro-F1 score of 94.2% under attack, yet it exhibits higher variability than CICIoMT2024 due to its smaller sample size and simulated client partitions. These results indicate that ATLAS-FL can perform well on IoMT devices and communication protocols, yet cannot be used to infer direct feature transfer or universal generalization across all IoMT devices.

Furthermore, to fully appreciate the results presented in the table, it is also important to consider the confidence intervals and run-level statistical data for each of the evaluated algorithms. The results support ATLAS-FL's claim that it limits the timing-induced utility loss of the evaluated attack model. However, these results do not demonstrate that ATLAS-FL performs better than all other methods across all potential datasets, models, attack intensities, or deployment configurations.

B. Buffered Asynchrony Versus Authenticated Timing Integrity

Differentiation between two core objectives is essential: efficient learning under benign stragglers versus secure admission under strategic delays (as outlined in Table XIV). FedBuff addresses the former, whereas ATLAS-FL solves the latter by authenticating every update's temporal context prior to aggregate release.

Under benign conditions, FedBuff leads with 94.1% Macro-F1, reaching the target in 74 rounds at 174 updates/min. ATLAS-FL follows at 93.7% F1 over 88 rounds (14 additional rounds and an 8.6% throughput drop), confirming FedBuff's natural efficiency advantage when late arrivals are non-adversarial.

However, under strategic delay and drop attacks, ATLAS-FL retains a superior 93.1% Macro-F1 over FedBuff (89.7%) and FedBuff-SecAgg (90.2%). Secure aggregation alone fails here because protecting content does not stop temporal manipulation. As highlighted in Fig. 8, FedBuff tolerates benign stragglers, whereas ATLAS-FL provides stronger utility under strategic timing manipulation.

This resilience stems from ATLAS-FL restricting P95 staleness to 1.1 rounds—an 83.8% reduction relative to FedBuff (6.8 rounds). Rather than discarding all delayed updates, ATLAS-FL permits bounded jitter, reserving hard rejection for explicit authentication and integrity failures.

TABLE XIV. ASYNCHRONOUS-BASELINE COMPARISON ON EDGE-IIOTSET

Method	Macro-F1: benign stragglers (%)	Macro-F1: strategic delay/drop (%)	Rounds to 92% F1	P95 staleness (rounds)	Updates/min
FedAvg	91.8	87.1	104	1.0	128
FedBuff	94.1	89.7	74	6.8	174
FedBuff-SecAgg	93.9	90.2	79	6.5	162
TriSAFE	93.5	91.8	92	1.7	151
ATLAS-FL	93.7	93.1	88	1.1	159

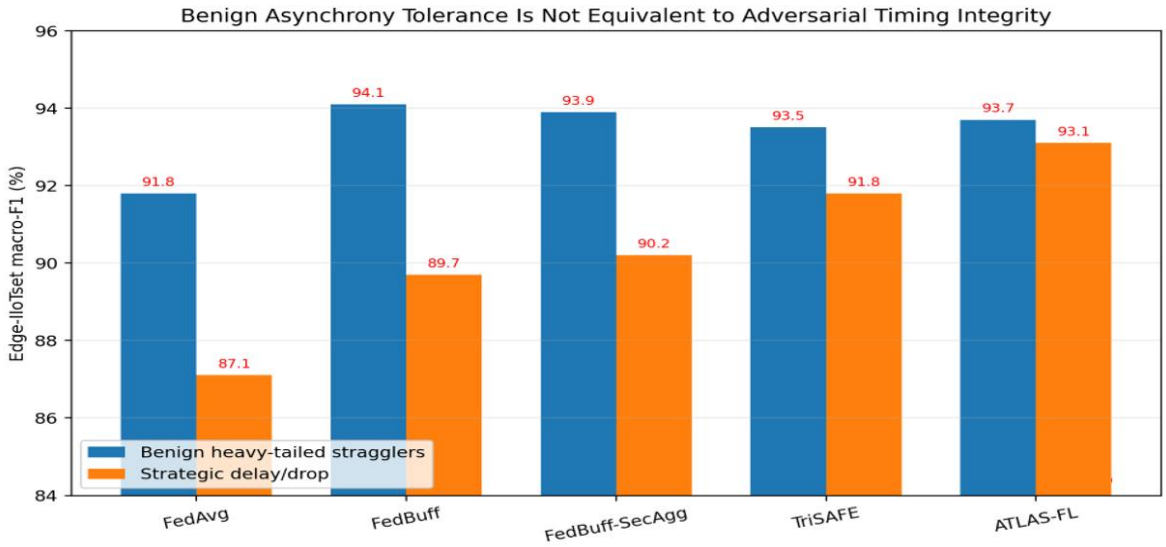

Fig. 8. FedBuff tolerates benign stragglers, whereas ATLAS-FL provides stronger utility under strategic timing manipulation.

C. Timing-Admission Security

As shown in Table XV, the results of the ATLAS-FL controller's processing of traffic with different types of timing manipulation are presented in terms of correctly handled messages, false escalations, and accepted manipulations. It is noteworthy that for this controller, these three parameters are considered individually, not cumulatively, since in practice, depending on the configuration, emphasis is placed on different aspects of protection.

For all six types of manipulation, including selective delay/drop, replay, slot shift, late forcing, and adaptive mixtures, the average value of correctly handled messages accounts for 93.8%. At the same time, the average number of accepted manipulations is 4.95%, with replay attacks having the lowest value (98.6% of correctly handled messages) and adaptive mixtures – the highest (91% of correctly handled messages).

Finally, false escalations of legitimate traffic account for 1.9 – 4.8% of all messages on average (3.8%), which is a reasonable value given the specified security policy. A lower value would lead to a higher number of manipulations that were not detected by the system, but such a policy would excessively penalize IoT/IoMT clients whose traffic was legitimately delayed due to network congestion.

TABLE XV. ATLAS-FL CONTROLLER OUTCOMES ON EDGE-IIOTSET

Attack	Correct handling (%)	False escalation (%)	Accepted manipulation (%)	Dominant action
Selective delay	94.3	3.8	5.7	buffer/reject
Selective drop	91.6	4.6	4.4	fixed-weight cover
Replay	98.6	1.9	1.3	hard reject
Slot shift	92.1	4.2	6.8	hard/score reject
Late forcing	95.0	3.6	4.9	cover/reject
Adaptive mixture	91.0	4.8	6.6	mixed actions

Replay has the best correct-handling rate (98.6%) with only 1.9% false escalations and 1.3% accepted manipulation. The reason for this outcome is the discrete nature of evidence for replay: a stale nonce, authentication token, or ciphertext digest can be checked against the freshness state maintained by the gateway. Decisions about replay are largely based on cryptographic evidence, not probabilistic timing logic.

As a result, selective drop also has a reasonably high correct-handling rate (91.6%) but a low 4.4% rate of accepted-manipulation events. In a selective drop, ATLAS-FL cannot force the dropped client to participate in the FL process, but the fixed-aggregation-coefficients assumption prevents the adversary from inflating the coefficients of the remaining clients. Thus, the main response to selective drop is not a reduction in the attacker's contribution but maintaining the commitment coefficient scheme by using zero-cover contributions.

Selective delay and late forcing have higher accepted-manipulation rates of 5.7% and 4.9%, respectively. These attacks are more challenging than replay because the timing perturbations could be caused by network congestion, clock drift, wireless channel characteristics, power-saving modes, or gateway queuing delays. Thus, ATLAS-FL uses a combination of normalized deviation from the temporal window and considers client-specific temporal behavior and the pressure on the privacy budget, rather than a strict deadline check.

Slot shifting and the adaptive mixture of attacks are the most challenging timing manipulations. Slot shifting has the highest accepted-manipulation rate of 6.8%, and the adaptive mixture has the lowest correct-handling rate of 91.0%, with an accepted-manipulation rate of 6.6%. The results demonstrate the importance of authenticated slot binding, as discussed earlier: when the ciphertext digest and authentication token are legitimate but bound to an incorrect slot in the schedule, the decision to accept or reject the contribution depends on consistency between the claimed slot identifier, round identifier, and committed temporal window. Fig. 9 provides the corresponding cross-method comparison of accepted manipulated-event rates.

The adaptive mixture tests a predefined controller-aware combination of delay, drop, replay, and slot-shift actions. Its 6.6% accepted-manipulation rate characterizes this tested mixed strategy; it should not be interpreted as a worst-case bound against an optimizing white-box adversary with unrestricted search over the controller scoring function and thresholds.

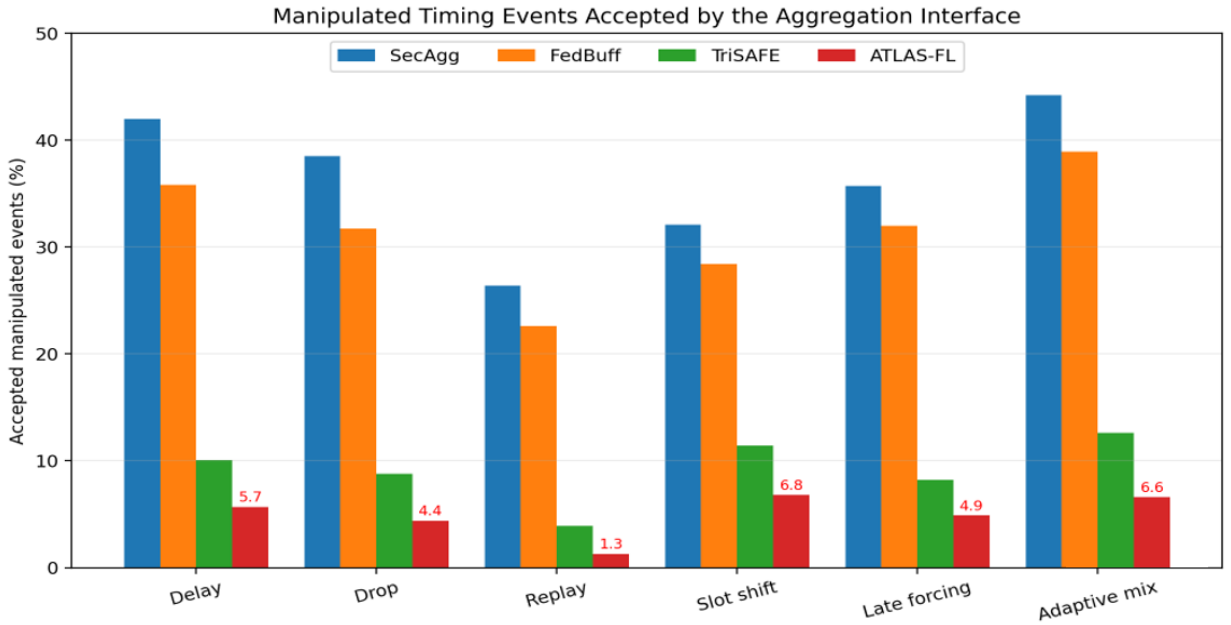

Fig. 9. Accepted manipulated-event rate across timing-aware and timing-blind methods.

The false-escalation rates below 5% are also promising, but they should not be considered safe zones. For large-scale deployments, even 3–5% of false escalations would create unacceptable overhead due to buffer releases, debugging, or recovery procedures. Thus, the threshold for individual-rate reporting should be determined through experimentation on a per-device basis, considering the traffic patterns, communication channel characteristics, clock precision, and other factors.

D. Participation Privacy and Release Consistency

Secure aggregation keeps individual client updates private, but it doesn't tell observers who participated in the updates. There are various ways observers could tell who participated. For instance, the timing of when the updates were released, the length of the messages sent, aborted updates, or other visible changes could tell an observer who was active in each round of learning. Table XVI examines three different release policies for those aggregate updates and the information about participation that they provide to an observer that monitors the gateway releasing those updates.

The variable-release policy without cover traffic provides an attacker with an ROC-AUC of 0.79±0.03. This indicates that the attacker has an advantage of 0.29 over guessing the participation of a given client randomly. Such a high advantage suggests there is substantial leakage of information about which clients participated in each round of learning. Even though the updates released are encrypted, any variations in the timing of those releases, the length of the messages, whether the round finished earlier or later, or whether a different output was released could be used to infer the participation of individual clients.

If the gateway enforces a fixed release time for the aggregate updates, the ROC-AUC decreases to 0.68±0.03. The decrease of 0.11 indicates that using a fixed release time can reduce some of the participation leakage. However, an attacker still has an advantage of 0.19 over guessing random participation. This remaining advantage could come from differences in the envelope length, whether the round aborted, how the payloads were structured, or if meaningful updates were released at all.

By using the ATLAS-FL zero-cover padded release policy, the ROC-AUC decreases further to 0.53±0.02. This is an advantage of just 0.03 over guessing random participation. When compared to the no-cover policy, the absolute AUC decreases by 0.26 and the advantage over guessing decreases by approximately 89.7%. The ROC-AUC decreases even further by 0.15 when compared to the fixed timing policy alone. These results suggest that the ATLAS-FL policy that combines fixed release time with equal-length encrypted envelopes and indistinguishable zero payloads is substantially better at concealing information about client participation than either fixed timing or a variable release time alone. Fig. 10 shows the corresponding participation-inference ROC curves for the three release policies.

TABLE XVI. PARTICIPATION-INFERENCE RESULTS

Release policy	Attacker ROC-AUC	Advantage over chance	Interpretation
No cover; variable release	0.79 ± 0.03	0.29	High participation leakage
Fixed time only	0.68 ± 0.03	0.19	Length/abort behavior still reveals state
ATLAS zero-cover padded release	0.53 ± 0.02	0.03	Near-chance under defined release observer

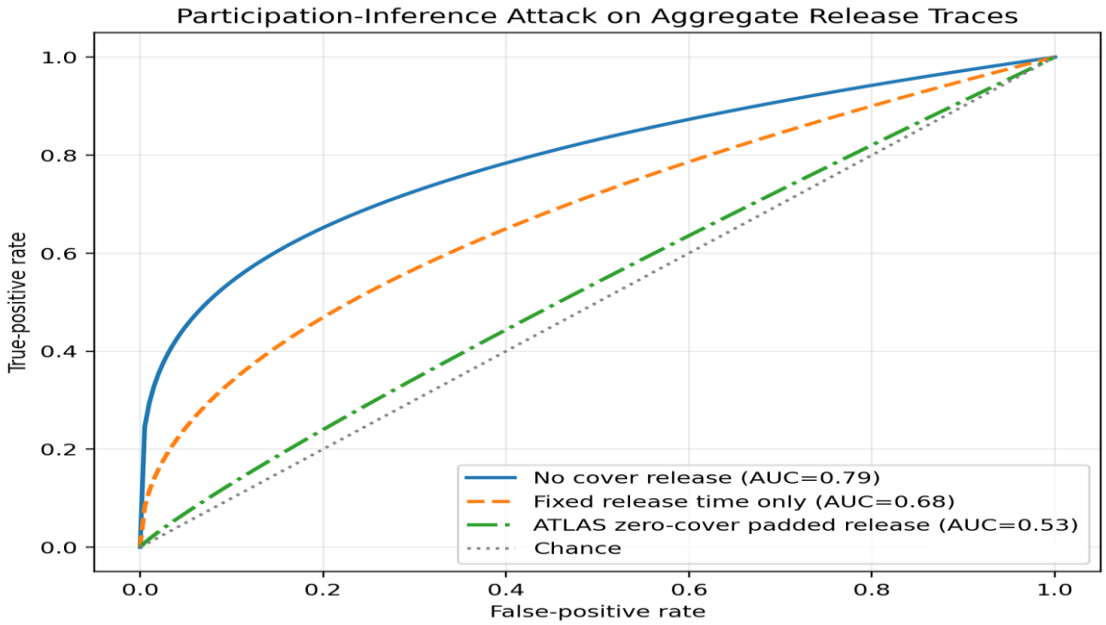

Fig. 10. Participation-inference ROC curves for alternative aggregate-release policies.

Although the AUC of 0.53 is considered to be near chance, it is still not perfectly private. The confidence interval of this result extends slightly beyond 0.50, and it is possible that the observer still has some information about participation from factors other than the release policy itself. These could include the timing of the implementation of certain operations, metadata from network layer protocols, information about queueing, or other factors that are correlated with client participation but not eliminated by the padding and zero payload of the release policy. Overall, this result indicates that the ATLAS-FL policy provides a bounded release trace that can be used for a limited type of privacy claim against an observer that does not have full network visibility.

It is important to consider the boundaries of this model of the observer. This experiment assumes that the observer is not able to correlate the activity of each client with the released gateway updates. A global passive observer with full network visibility could still potentially determine which clients participated based upon their uplinks to the gateway. To defend against such a global observer would require additional privacy-preserving mechanisms such as cover traffic from clients, the use of routing networks, providing synchronized transmission opportunities for all clients, or defenses against network traffic analysis techniques.

The results of these experiments also highlight the difference between participation privacy and differential privacy. Differential privacy refers to the privacy of the data that is released from a model, whereas participation privacy relates to the privacy of the fact that a client participated in the training of that model. Both concepts are essential for achieving a comprehensive privacy guarantee for clients in a federated learning framework. However, achieving privacy in one aspect does not necessarily mean that the clients are also achieving it in the other.

E. DP-Relevant Stability and Missing-information Cost

Table XVII evaluates four stability indicators under selective client absence. The purpose of this analysis is not to claim that fixed weighting independently provides differential privacy. Instead, it examines whether timing-driven cohort changes alter the aggregation structure in ways that complicate clipping-based sensitivity bounds, noise calibration, and repeated-round privacy accounting.

TABLE XVII. AGGREGATION-STABILITY INDICATORS

Indicator	Renormalized baseline	FedBuff-SecAgg	TriSAFE	ATLAS-FL
Weight inflation	0.310	0.146	0.073	0.018
Aggregate drift	0.287	0.151	0.124	0.091
Sensitivity-change proxy	0.264	0.133	0.098	0.056
Release variation	0.221	0.128	0.101	0.073

The largest difference is in the weight-inflation indicator: 0.310 for the renormalized baseline versus 0.018 for ATLAS-FL, a reduction of 94.2%. Relative to FedBuff-SecAgg's 0.146, ATLAS-FL reduces the weight-inflation by 87.7%, and by 75.3% relative to TriSAFE's 0.073. This result is explained by the choice of coefficients: using those committed over the selected cohort rather than reestimated over the observed survivors. Fig. 11 summarizes the four reported aggregation-stability indicators.

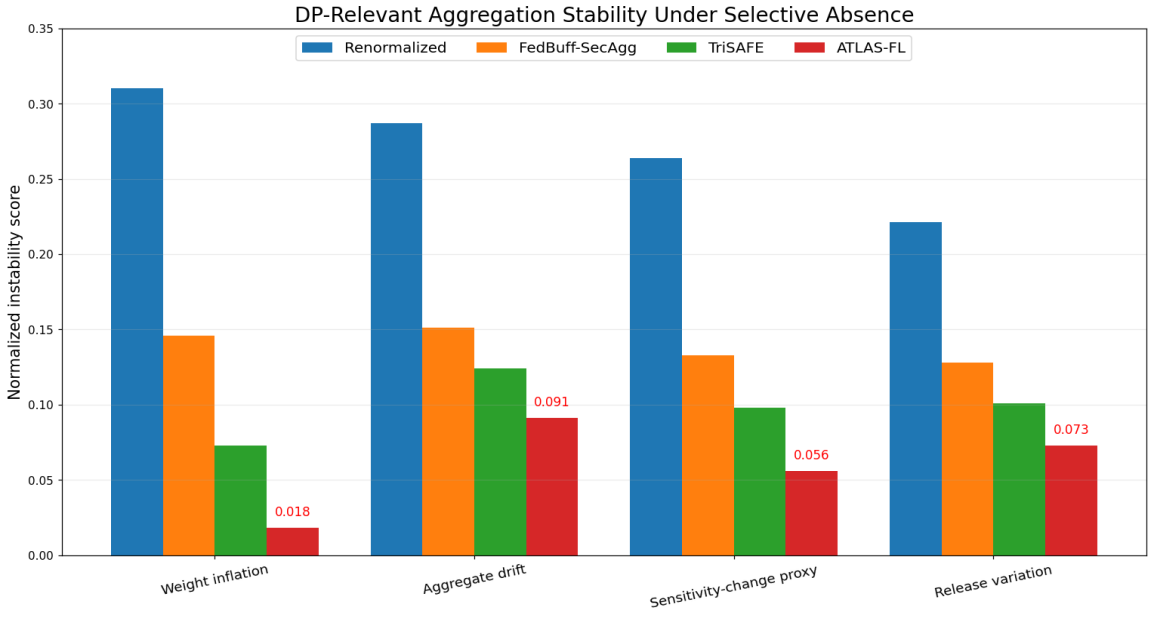

Fig. 11. DP-relevant aggregation stability under selective absence.

ATLAS-FL substantially improves operational and privacy stability across all three drift metrics compared to the renormalized baseline:

Aggregate Drift: Reduced by 68.3% (from 0.287 to 0.091). The value remains non-zero because zero-cover contributions preserve client weight without recreating the missing update's exact magnitude.

Sensitivity-Change Proxy: Reduced by 78.8% (from 0.264 to 0.056), significantly outperforming FedBuff-SecAgg (57.9%) and TriSAFE (42.9%). As proven in Proposition 2, pre-committing coefficients bounds sensitivity, whereas post-hoc renormalization relies dangerously on surviving clients.

Release Variation: Reduced by 67% (from 0.221 to 0.073), stabilizing release dynamics and preventing adversaries from inferring individual client absence by analyzing arrival differences.

The remaining aggregate drift must be interpreted through the missing-client deviation bound:

$$\|A_t^{\text{ideal}} - A_t^{\text{ATLAS}}\|_2 \leq C \sum_{i \in M_t} \alpha_{it} \quad (14)$$

As demonstrated in Eq. (14), weight deviation depends directly on the clipping bound and the committed weight of missing clients—meaning losing high-weight clients impacts utility more than losing low-weight ones.

ATLAS-FL provides weight stability, not update recovery. It prevents adversaries from inflating survivor influence and bounds sensitivity, but it does not reconstruct missing data.

Consequently, differential-privacy guarantees remain conditional on the stated adjacency, sampling, clipping, Gaussian mechanism, and composition procedure. The ε values in Table X were computed from the executed sampling, clipping, noise, and 120-round composition configuration; the stability indicators in Table XVII are not themselves privacy guarantees.

F. *WUSTL Network-Only Versus Network-Plus-Biometric Sensitivity*

Table XVIII reports the WUSTL network-only versus network-plus-biometric sensitivity analysis.

Biometric features improve clean discrimination but provide only a modest attacked-round gain and slightly increase aggregate drift. They are therefore treated as a secondary sensitivity analysis, not as a required input to the timing protocol or a clinical endpoint.

TABLE XVIII. WUSTL REPRESENTATION SENSITIVITY

Representation	Clean macro-F1 (%)	Attacked macro-F1 (%)	Aggregate drift	Participation AUC
Network-only (35 features)	95.7 ± 0.4	94.2 ± 0.5	0.063	0.54 ± 0.03
Network + biometric (43 predictors)	97.0 ± 0.3	94.7 ± 0.5	0.071	0.55 ± 0.03

G. *Differential-Privacy Utility Profile*

The evaluated Edge-IIoTset operating point uses the executed privacy configuration reported in Table X (ε=4.6 at $\delta=10^{-5}$). Fig. 12 reports the corresponding privacy-utility profile; lower ε represents stronger Gaussian perturbation, whereas higher ε weakens the perturbation and improves attacked utility within the evaluated range.

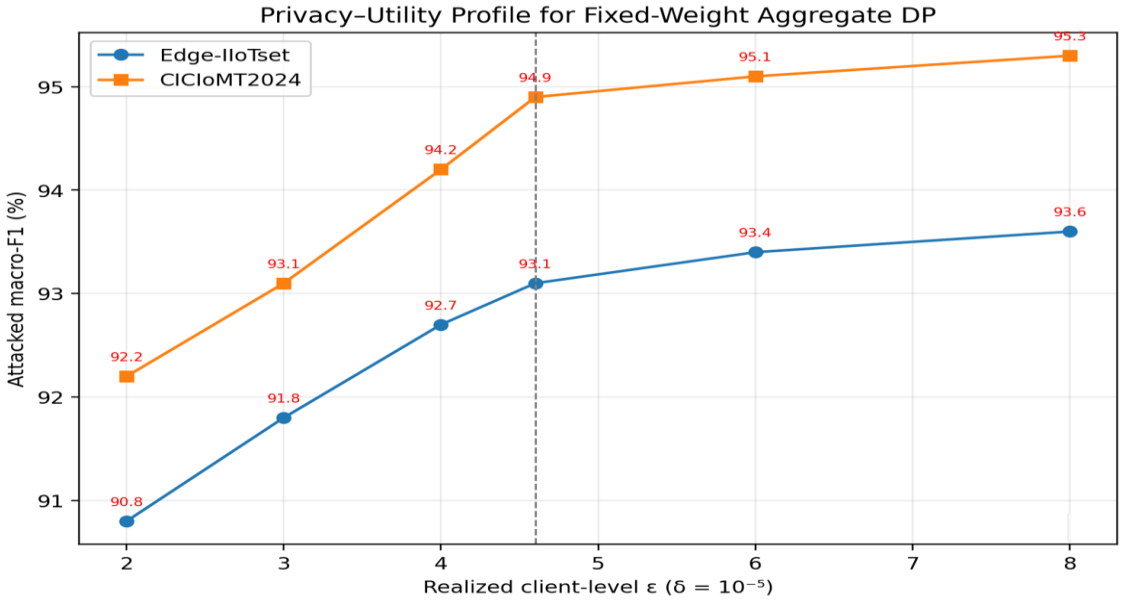

Fig. 12. Privacy–utility profile for Edge-IIoTset and CICIoMT2024.

H. Component Ablation

The ablations separate four functions. Token binding primarily affects replay and slot integrity; the controller governs admission; fixed weights govern aggregate stability; and cover release governs participation privacy. Table XIX reports the component-level ablation results.

I. Cryptographic and Operational Overhead

Table XX reports the cryptographic microbenchmarks, Table XXI reports the four overhead metrics at the 40-client reference point, and Fig. 13 reports scalability for the metrics recorded across multiple cohort sizes.

The microbenchmarks used an Intel Core i7-12700H gateway, Ubuntu 22.04, Python 3.11, OpenSSL 3.0-backed cryptographic primitives, a 25,500-parameter update vector, 10,000 repetitions after 500 warm-up iterations, and median latency with bootstrap 95% confidence intervals.

TABLE XIX. COMPONENT ABLATION ON EDGE-IIOTSET

Variant	Attacked macro-F1 (%)	Accepted manipulation (%)	Weight inflation	Participation AUC
Full ATLAS-FL	93.1	5.7	0.018	0.53
No authenticated token binding	91.8	14.6	0.038	0.55
No timing-risk controller	88.7	31.8	0.184	0.66
Renormalized aggregation	90.2	18.9	0.310	0.61
No cover release	92.5	7.1	0.032	0.79

TABLE XX. CRYPTOGRAPHIC MICROBENCHMARKS

Operation	Latency	Measurement unit
Client X25519 + HKDF setup	0.11 ms	once per cohort
HMAC generation	0.014 ms	per update
ChaCha20 mask expansion	0.22 ms	per update vector
Gateway HMAC/window verification	0.024 ms	per client
Shamir dropout recovery	2.6 ms	40-client cohort; 6 recovered clients
Fixed-length release envelope	0.12 ms	per round

TABLE XXI. OVERHEAD RELATIVE TO TIMING-BLIND SECAGG AT 40 SELECTED CLIENTS

Method	Round/flush latency (%)	Communication (%)	Gateway CPU (%)	Memory (%)
TriSAFE	4.6	2.3	5.8	3.2
FedBuff-SecAgg	-4.2	2.1	6.1	5.6
ATLAS-FL	5.9	2.8	7.4	4.1

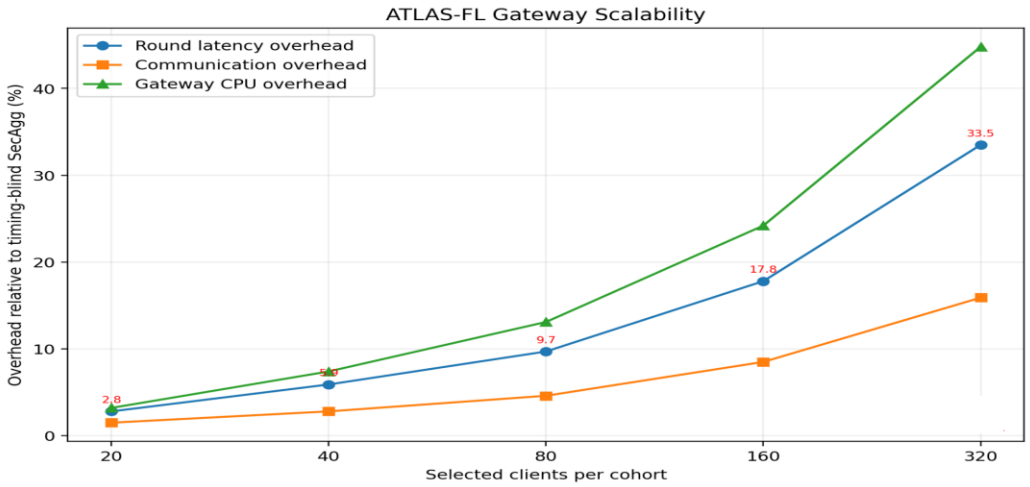

Fig. 13. ATLAS-FL gateway scalability. The principal cost grows with the selected cohort size.

Fig. 13 plots round/flush-latency, communication, and gateway central processing unit (CPU) overhead across the evaluated cohort sizes. Memory overhead was recorded for the 40-client reference point in Table XXI but not as a separate multi-cohort scalability series; no broader memory-scaling claim is made.

J. Statistical Evidence

Table XXII reports the paired run-level statistical evidence from the 20 completed executions. The moderate margin over TriSAFE is more credible than a universal superiority claim. The largest effects occur in outcomes directly targeted by ATLAS-FL: manipulated-event admission, weight inflation, and participation inference.

TABLE XXII. PAIRED RUN-LEVEL STATISTICAL EVIDENCE (20 EXECUTIONS; HOLM ADJUSTED)

Comparison	Outcome	Mean difference	95% CI	Adjusted p	Paired d_z	Magnitude
ATLAS-FL vs SecAgg	Edge attacked macro-F1	+6.50 points	[+6.23, +6.77]	<0.001	10.93	large
ATLAS-FL vs FedBuff-SecAgg	Edge attacked macro-F1	+2.90 points	[+2.67, +3.14]	<0.001	5.92	large
ATLAS-FL vs TriSAFE	Edge attacked macro-F1	+1.30 points	[+1.06, +1.53]	<0.001	2.43	large
ATLAS-FL vs SecAgg	Accepted manipulated-event rate	-34.72 points	[-35.62, -33.82]	<0.001	-18.02	large
ATLAS-FL vs renormalized	Weight-inflation score	-0.29 score	[-0.30, -0.28]	<0.001	-17.88	large
ATLAS-FL vs no-cover	Participation-inference AUC	-0.26 AUC	[-0.27, -0.25]	<0.001	-14.56	large
ATLAS-FL vs FedBuff-SecAgg	CICIoMT attacked macro-F1	+2.90 points	[+2.69, +3.12]	<0.001	6.35	large

VIII. DISCUSSION

A. Relationship Between Evidence and the Research Gap

The results quantify the distinction between benign asynchrony and adversarial temporal integrity. On Edge-IIoTset under heavy-tailed benign stragglers, FedBuff reaches a macro-F1 of 94.1%, slightly above ATLAS-FL at 93.7% and TriSAFE at 93.5%. Under strategic delay and drop, however, ATLAS-FL retains 93.1%, whereas FedBuff falls to 89.7%, FedBuff-SecAgg to 90.2%, and FedAvg to 87.1%. This 3.4-point margin over FedBuff and 6.0-point margin over FedAvg directly addresses RO6 by showing that throughput-oriented asynchrony does not by itself secure the timing interface. The attack-level evidence in Table XV is consistent with that conclusion: replay has the lowest accepted-manipulation rate at 1.3%, while slot shift and adaptive mixtures remain the hardest settings at 6.8% and 6.6%, respectively.

The formal analysis provides the missing theoretical link. The empirical controller reduces accepted manipulation, but the security argument explains why specific transcript changes should fail before the controller score is even applied. In particular, the HMAC-bound token authenticates round, slot, window, nonce, and ciphertext digest; the corresponding reduction in (13) ties temporal-binding forgery to HMAC unforgeability and hash collision resistance, while (14) bounds the residual missing-information effect by the total absent weight mass. The numerical stability evidence complements this proof layer: ATLAS-FL reduces the weight-inflation score to 0.018, compared with 0.073 for TriSAFE, 0.146 for FedBuff-SecAgg, and 0.310 for the renormalized baseline.

B. Added Value and Boundary Relative to TriSAFE

TriSAFE remains the closest and strongest comparator. The new results should therefore be interpreted primarily against that baseline rather than against timing-blind methods alone. Under attacked conditions, ATLAS-FL exceeds TriSAFE by 1.3 points on Edge-IIoTset (93.1% versus 91.8%), 1.3 points on N-BaIoT (95.8% versus 94.5%), 1.6 points on CICIoMT2024 (94.9% versus 93.3%), and 1.3 points on WUSTL-EHMS-2020 (94.2% versus 92.9%). The improvement is not presented as a large accuracy gain in isolation; its importance is that the mechanism-level additions—slot-specific binding, explicit replay-cache admission, fixed-weight no-renormalization, and padded zero-cover release—produce better security behavior at the same time as these utility gains. Table XVII shows the same pattern on stability indicators, where ATLAS-FL lowers the sensitivity-change proxy to 0.056 versus 0.098 for TriSAFE and 0.264 for the renormalized baseline.

C. Replication Across IoT, IIoT, and IoMT

CICIoMT2024 provides the strongest justification for restoring IoMT to the title because it contributes an attacked macro-F1 of 94.9% after a clean macro-F1 of 96.4%, corresponding to a 1.5-point reduction under active timing manipulation. The same qualitative pattern appears on the other benchmarks: the clean-to-attacked drop is 1.1 points on Edge-IIoTset (94.2% to 93.1%), 1.4 points on N-BaIoT (97.2% to 95.8%), and 1.5 points on WUSTL-EHMS-2020 (95.7% to 94.2%). This replication is important because the study is not claiming a universal feature space or zero-shot transfer; instead, it shows that the same ATLAS-FL protocol remains effective when the local IDS is retrained independently across IoT, IIoT, and IoMT conditions.

D. Fixed Weights, Zero Cover, and Missing Information

No-renormalization prevents the adversary from inflating survivor importance with a magnitude that itself is now visible in absolute terms. According to Table XVII, the renormalized baseline has a weight-inflation score of 0.310, an aggregate-drift score of 0.287, and a sensitivity-proxy score of 0.264, compared to 0.018, 0.091, and 0.056 for ATLAS-FL. The same conclusion explains the ablation study result: replacing fixed

weights with renormalized aggregation reduced attacked macro-F1 from 93.1% to 90.2%, while increasing accepted manipulation from 5.7% to 18.9%. Eq. (14) also explains why zero cover is a bounded rather than reconstructive adjustment: ATLAS-FL suppresses the contribution of absent clients, but cannot reconstruct the information that was never contributed to the round. This interpretation is limited to the tested absence conditions and does not imply preserved convergence or detection utility under arbitrary missing-weight mass.

E. Differential Privacy Interpretation

Fixed weights do not provide differential privacy by themselves; they stabilize the sensitivity used by the accountant. Fig. 12 shows the expected privacy-utility direction: attacked macro-F1 increases as ε increases and Gaussian perturbation weakens. For Edge-IIoTset, macro-F1 rises from 90.8% at ε=2.0 to 93.6% at ε=8.0; for CICIoMT2024 it rises from 92.2% to 95.3% over the same evaluated profile. Participation privacy remains distinct from output differential privacy: Table XVI shows attacker ROC-AUC decreasing from 0.79 without cover to 0.68 with fixed time only and to 0.53 under the padded zero-cover release. The latter result supports only the bounded release-observer claim defined in Section V-E, not global network-level participation privacy.

F. Operational and Deployment Implications

The controller and replay state reside in the gateway, where the round-level cryptographic and timing evidence can be archived for auditing. At the evaluated scale of 40 selected clients, ATLAS-FL adds 5.9% to the round latency, 2.8% to the communication overhead, 7.4% to the gateway CPU load, and 4.1% to the memory consumption, compared to the timing-blind SecAgg. Fig. 13 shows the measured multi-cohort trends for round/flush latency, communication, and gateway CPU; memory is reported only at the 40-client reference point in Table XXI. The plotted metrics rise with cohort size, with CPU and queue pressure becoming more pronounced at the largest evaluated cohorts. Thus, the practical deployment of ATLAS-FL depends on the availability of authenticated time synchronization and clock drift bounding, as well as the operational window selection, rather than the properties of the protocol logic itself.

G. Error and Safety Interpretation

Attacked macro-F1 is not the sole metric of interest for secure aggregation deployment in production. The reported security metrics therefore complement attacked macro-F1 rather than serving as interchangeable measures of deployment safety. Specifically, while on Edge-IIoTset the attacked macro-F1 of 93.1% remains high, the attack acceptance varies from 1.3% to 6.8% depending on the attack vector, and the false-escalation rates are between 1.9% and 4.8%. Additionally, the ablation study now shows the impact of individual components on the system's ability to withstand attacks: their removal leads to the drop of attacked macro-F1 from 93.1% to 88.7%, an increase in attack acceptance from 5.7% to 31.8%, and participation AUC from 0.53 to 0.79 for the same input attack vectors. For the application areas such as healthcare, this type of analysis helps characterize the allocation of risk better: the specific failure modes are known, and their likelihood can be evaluated against the domain-specific threat model.

IX. Limitations and Threats to Validity

Table XXIII summarizes the principal threats to validity and the resulting claim boundaries.

TABLE XXIII. Threats to Validity and Claim Boundaries

Threat	Limitation / boundary
Construct validity	The study evaluates timing-admission integrity, aggregate stability, release-trace inference, and IDS utility. It does not cover all FL security properties.
Cryptographic validity	The reductions assume correct implementations of HMAC, X25519/HKDF, mask generation, Shamir recovery, and payload encryption. Side channels and implementation bugs remain outside the proof. Enrollment, key rotation, revocation, compromised-device recovery, device replacement, and authentication-state synchronization are delegated to an external trusted key-management service and are outside the protocol proof.
Controller validity	Calibration uses simulated benign jitter and timing attacks. Robustness claims are limited to the tested client-specific latency model; untested heavy-tailed, bursty, correlated, multimodal, or shifted delay distributions and stronger adaptive evasion may change the decision boundary.
IoMT external validity	CICIoMT2024 is a realistic multi-protocol testbed, but it is not a production hospital network. WUSTL clientization is simulated rather than multi-institutional.
Asynchronous baseline validity	FedBuff-SecAgg is a controlled experimental variant, not a claim of a new published algorithm. Parameter matching must be documented.
Statistical validity	Twenty independent paired runs were executed. Statistical inference is computed at the run level with Holm adjustment; clients, rounds, and timing events are not treated as independent replicates.
Operational validity	Overhead depends on model size, client count, cryptographic library, gateway hardware, and clock quality. Fixed-point correctness additionally assumes that the configured scale and modulus satisfy the stated no-wrap bound; the analytic quantization bound does not constitute a separate convergence guarantee.

Data Availability

Edge-IIoTset, N-BaIoT, CICIoMT2024, and WUSTL-EHMS-2020 are third-party research datasets available from their original maintainers under the applicable terms [34], [35], [16], [17]. The corresponding preprocessing, client-partition, and attack-schedule specifications are documented in the experimental methodology and retained with the study records.

Funding

No external funding was received for this study.

Competing Interests

The authors declare that they have no competing interests.

1) Ethics approval: This study does not involve human participants, human data, animal subjects, or clinical intervention; therefore, ethics approval is not applicable.

2) Code availability: The prototype implementation and experiment scripts are available from the corresponding author upon reasonable request.

AUTHORS' CONTRIBUTIONS

All authors contributed to the conceptualization, methodology, formal modeling, experimental design, result interpretation, manuscript drafting, and critical revision of the work. All authors reviewed and approved the final manuscript.

1) Declaration of AI-assisted technologies in the writing process: During the preparation of this manuscript, the authors used Paperpal for language editing, grammar checking, and improving the overall readability of the text. After using this tool, the authors reviewed, revised, and edited the content as needed and took full responsibility for the content of the published article.

APPENDIX A. ELABORATED FORMAL SECURITY ARGUMENTS

A. 1 Temporal-binding Game

The challenger provides authentication keys and answers commitment queries on arbitrarily chosen messages. The adversary wins by outputting a verifying tuple whose authenticated field vector has not been previously queried, or by producing a modified ciphertext whose authenticated digest has already been seen. The reduction keeps track of all queried field vectors and outputs a fresh forgery to the HMAC challenger when the adversary succeeds. A modified ciphertext with the same digest is also a collision for H.

A. 2 Replay and Slot Substitution

Round nonces are sampled independently and stored for reference alongside the replay cache. A replayed tuple from round t′ will either retain the original nonce and be rejected during the fresh round's verification step or contain a different nonce, round, or slot and be required to produce a valid tag. Slot substitution is similar, but the substituted value is s_(i,t).

A. 3 Secure Aggregation under Timing Rejection

Timing rejection allows the gateway to modify the dropout set before performing recovery. The gateway reveals G_t and M_t, and surviving clients release only the shares necessary to cancel the masks corresponding to M_t. The pairwise masks between accepted clients cancel out when summed, while the private masks of the accepted clients remain unreconstructed. The confidentiality of client contributions thus maintains the secure-aggregation confidentiality guarantee under the same collusion bound.

A. 4 Release-trace Game

The challenger samples a bit b hidden from the adversary, which determines whether the release-trace envelope is constructed around a real or dummy payload. In either case, the trace contains the same scheduled release time, size, authentication parameters, and encryption algorithm. Any advantage the adversary gains from distinguishing real from dummy traces must come from differences in timing, lengths, abort behaviors, or other implementation details. An empirical measurement of this advantage is given by the observer attack of Section VII-D.

Adaptive Virtual Reality Exposure Therapy Using AI-Driven Anxiety Prediction from Physiological and Behavioral Data

***Abstract*—All mental health disorders; anxiety disorders rank as the most common ones. They affect the cognitive functions of an individual as well as their ability to socialize or live in a quality manner. Exposure Therapy happens to be one of the most effective methods aimed at treating fears, phobias, and traumatic memories; however, the traditional approach to exposure therapy and VRET is unable to modify the exposure intensity in accordance with the situation that is occurring with the patient, thus making this method ineffective. This article suggests a solution to the problem by creating AVRET, or Adaptive Virtual Reality Therapy, which will provide the opportunity to predict the anxiety of the patient in real-time through their physiological (HR, HRV, GSR) and behavioral (eye-tracking, blink rate, pupil dilation) indicators. The suggested system uses an LSTM deep learning model to evaluate the amount of anxiety and change the scenario, distance to objects, sounds, or level of difficulties based on the current anxiety evaluation.**

***Keywords*—Virtual reality exposure therapy; LSTM; anxiety prediction; physiological computing; closed-loop systems; multimodal fusion**

I. Introduction

A cause of concern in the healthcare system is anxiety disorders that affect emotional well-being, cognitive abilities, and interpersonal relationships. Standard treatments for anxiety disorders include cognitive behavioral therapy (CBT) and exposure therapy; however, traditional exposure therapy does not have complete control over the environment, relies on the therapist's thorough assessment of the patient's condition, and does not provide tailored service, in addition to creating safety problems [1]. Virtual reality exposure therapy (VRET) overcomes some of the problems identified in traditional therapy by providing a safe environment for patients to practice the skills they acquired in therapy. Although VR exposure therapy has proved treatment effective, many of the existing systems remain rigid and unable to respond to the patient's physiological signals to adapt to the effectiveness of treatment. Advances in AI, deep learning, and physiological computing now allow emotional state to be inferred from signals such as heart rate (HR), heart rate variability (HRV), galvanic skin response (GSR), pupil diameter, eye tracking, eye blink rate, and motion.

This study proposes a closed-loop Adaptive VR Exposure Therapy (AVRET) framework that combines multimodal physiological sensing, behavioral analysis, LSTM-based anxiety prediction, and adaptive VR control with real-time feedback. An LSTM network extracts temporal patterns from the multimodal stream to estimate anxiety, and the adaptive controller uses this estimate to continuously tune scene complexity, object motion, loudness, and exposure level, improving personalization, comfort, safety, and interactivity relative to static VR therapy [2].

This research proposes a closed-loop intelligent healthcare framework combining physiological monitoring, behavioral analysis, deep-learning-based emotion assessment, adaptive VR control, and feedback, aimed at maximizing patient emotional comfort during therapy [3].

The main contributions of this work are: 1) A multimodal physiological and behavioral sensing approach for real-time anxiety measurement; 2) Integration of HR, HRV, GSR, eye-tracking, blink frequency, pupil dilation, and motion for holistic emotional awareness; 3) An LSTM-based deep learning model for temporal anxiety prediction; 4) A closed-loop VR controller that modifies the environment based on emotional state; 5) Improved personalization, emotional safety, and adaptive interaction in immersive healthcare; and 6) An AI-powered intelligent mental healthcare framework combining VR and deep learning.

II. Literature Survey

A. Prevalence and Exposure Therapy

Anxiety disorders affect an estimated 301 million people worldwide (WHO, 2023), including GAD, panic disorder, social anxiety disorder, specific phobias, agoraphobia, and PTSD, and account for 28.6 million DALYs annually [4]. In the United States alone, direct and indirect costs exceed $42 billion per year, yet fewer than 40% of patients receive effective treatment due to shortages of specialists, cost, stigma, and limited access [5].

Exposure therapy is still the standard treatment according to the reciprocal inhibition theory of Wolpe as well as modern models of inhibitory learning. The key factor behind the effectiveness of this technique is the intensity of the exposure, its performance without any attempts to escape the fear [6], and the level of predictability. However, application of the exposure method has a number of difficulties, such as real-world issues, lack of standardization, and thus reliance on subjective self-report tools, including the SUDS scale [7].

B. VRET and Physiological Affect Recognition

Virtual Reality Exposure Therapy (VRET), which was first created in the 1990s, allows the successful reproduction of real-life situations that provoke fear in a simulated 3-dimensional environment utilizing head-mounted displays and advanced techniques for tracking movements and spatial sounds, granting the doctor absolute control over the complexity and the intensity of the therapy process [8]. Reviews indicate the results of VRET are comparable to those obtained with in-vivo exposure, although it provides safety and accessibility for phobias, social anxiety, panic disorder, and PTSD. Nevertheless, the majority of existing systems are still based on rigid therapist-controlled procedures and have low adaptability towards rapid changes in users' emotional conditions.

It has been suggested that physiological computing can bridge the gap in anxiety and stress by activating the autonomic nervous system, bringing about measurable changes such as a rise in heart rate and a drop in heart rate variability, an increase in GSR (from normal skin conductance level and phasic responses), and changes in pupillary dilation, rate of blinking, and gaze pattern. Since no stand-alone solution has managed to capture the anxious state completely — cardiac signals are disturbed by motion; electrodermal measures have a slow response (and ocular signal changes are associated with attention) — using a combination of physiological signals can greatly direct the quest for an effective solution [9].

III. Problem Statement

Increasing stress, trauma, and lifestyle pressures have increased the rate of anxiety disorders, yet CBT and exposure therapy remain limited by dependence on therapists, poor scalability, and an inability to track patients' emotional state during treatment. VRET increases accessibility and control and has been used efficiently to treat phobias, PTSD, and social anxiety [10], but existing systems do not configure exposure to the patient's steadily changing emotional condition. Because emotional responses are highly individualized, static exposure risks either overexposure, increasing distress, or underexposure — limiting therapeutic effect. Furthermore, most anxiety-prediction approaches rely on a single physiological signal or offline analysis, limiting robustness, and common machine learning models struggle to capture long-term dependencies in physiological and behavioral data flow. These gaps motivate an Adaptive VR Exposure Therapy system that can track multiple modalities, predict anxiety in real time using deep learning, and adapt the environment continuously.

IV. Proposed Model

This study describes AVRET, a smart system for measuring a user's mood and making modifications to the VR environment based on the predicted level of anxiety. This is unlike traditional VR therapy, which uses preset conditions and relies on therapists, as AVRET automatically assesses physiological and behavioral parameters and adapts the environment in real-time using artificial intelligence [11]. Fig. 1 depicts a relevant closed-loop BCI VR setup whereby EEG is captured, feature extraction is done, and the classified state is returned to the user as visual, auditory, and haptic feedback. AVRET operates on the same closed-loop concept of functioning but relies on peripheral physiological signals as opposed to central signals.

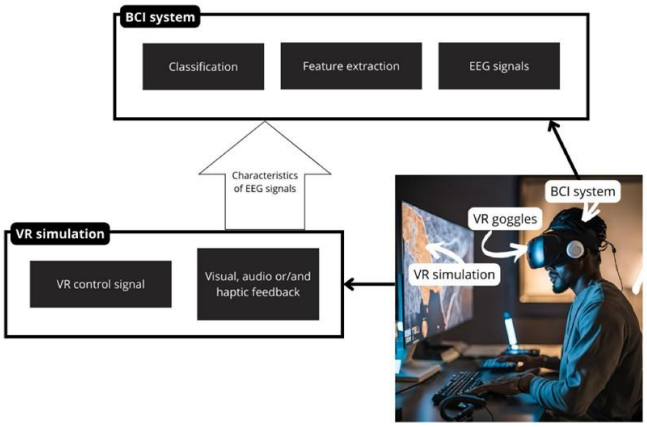

Fig. 1. Adaptive VR environment.

Fig. 2 shows the overall AVRET pipeline: User in VR Environment, Multimodal Sensor Input, Data Pre-processing, Feature Extraction, Multimodal Feature Fusion, LSTM-based Anxiety Prediction, Anxiety Classification, VR Adaptive Controller, VR Environment Adjustment, and a Feedback Loop.

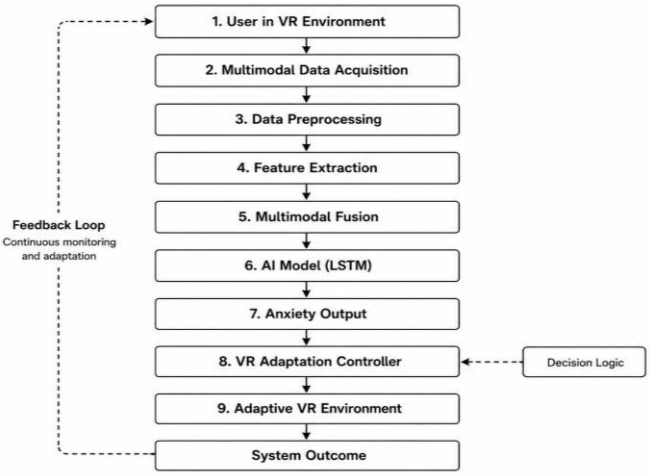

Fig. 2. Proposed adaptive virtual reality anxiety detection and adaptation pipeline.

The user is part of a virtual reality simulation (public speaking, crowds, heights, closed spaces, etc.) using head-mounted displays and motion tracking that enables emotional monitoring at any time. Multi-modal sensors continuously measure HR, HRV, GSR, eye-tracking, blink rate, pupil dilation, and head movement since anxiety, stress, and cognitive load occur simultaneously in multiple physiological systems. However, in order to use the raw signals, a number of processing techniques are applied to achieve proper filtering, smoothing, and alignment of the signals [12].

By extracting features, the latter signals can be converted into different statistical, temporal, and behavioral manifestations, such as mean/peak HR, HRV statistics, GSR peak attributes, blink frequency, pupil dilation change, fixation

time, and motion intensity. This way, cardiovascular, electrodermal, oculometric, and motion features are combined into a single emotional model using a fusion layer to make it more effective than one of the techniques [13]. The agreed features are then processed by the LSTM network that uses internal memory and does not analyze feature vectors like other models using the data multiplicity principle.

The level of anxiety predicted is sorted into Low, Medium and High and forwarded to the VR Adaptation Controller. In accordance with the level of anxiety, the VR adaptation controller alters the virtual environment accordingly: low level of anxiety – increases exposure intensity, medium level of anxiety – keeps the environment the same, high level of anxiety – lowers the stress level in the environment: scene complexity, lighting, object speed, sound, crowd density, stimulus object distance and exposure time are modified to reflect this adaptation. The process of continual monitoring leads to an adaptive approach which ensures the idea of personalization and the principle of comfort and safety of users. Constant feedback between monitoring, predicting, adapting, and re-evaluating proves that the system is more flexible as compared to static one-time VR therapy systems and methodologies [14]

V. Methodology

The AVRET framework proposed here is made of six stages as follows: obtaining the multimodal data, preprocessing the data, extracting features, combining the different modalities' features, performing anxiety prediction based on LSTM, and implementing a closed-loop adaptive VR control.

A. Data Acquisition, Preprocessing, and Key Formulas

In the process of virtual reality (VR) sessions, several multimodal physiological and behavioral signals are simultaneously collected in real time; these include the parameters of heart rate (HR), heart rate variability (HRV), reticular activation system (RAS), eye parameters (eye tracking), blink frequency, and pupil expansion. The captured data is filtered to remove noise, smoothed, excessive outliers removed, missing data filled in, and synchronized in time, ensuring a consistent format for analysis. Essential equations used for this purpose are as follows:

$$HR = 60 / RR \quad (RR = \text{interval between consecutive heartbeats})$$

$$HRV = \sqrt{[(1/N)\,\Sigma\,(RR_i - \text{mean}(RR))^2]} \quad \text{over } N \text{ samples}$$

$$GSR = SCL + SCR \quad (\text{tonic level} + \text{phasic response})$$

$$\text{Blink Rate} = \text{Number of Blinks} / \text{Time}$$

$$\text{Pupil Dilation (PD)} = P_{current} - P_{baseline}$$

$$\text{Normalization: } X_{norm} = (X - X_{min}) / (X_{max} - X_{min})$$

B. Feature Extraction and Fusion

Cardiovascular features consist of average/peak HR, RR-interval and HRV statistics, and frequency domain parameters; electrodermal features include skin-conductance level, GSR peak frequency, amplitude, and recovery; behavioral/ocular features include eye blink rate, pupil-dilation rate, fixation duration, gaze pattern, and head-movement intensity. These are fused into a single vector, F_fusion = [F_HR, F_GSR, F_Eye], improving emotional encoding, accuracy and robustness over any single modality.

C. LSTM Anxiety Prediction

An LSTM network predicts anxiety from the sequential multimodal features because it retains sequential dependencies via internal memory cells rather than treating each feature vector independently [16]. Its gating equations are:

$$f_t = \sigma(W_f[h_{t-1},x_t]+b_f) \quad (forget)$$

$$i_t = \sigma(W_i[h_{t-1},x_t]+b_i) \quad (input)$$

$$\tilde{C}_t = \tanh(W_c[h_{t-1},x_t]+b_c) \quad (candidate)$$

$$C_t = f_t \cdot C_{t-1} + i_t \cdot \tilde{C}_t \quad (cell\ update)$$

$$o_t = \sigma(W_o[h_{t-1},x_t]+b_o) \quad (output)$$

$$h_t = o_t \cdot \tanh(C_t) \quad (hidden\ state)$$

The model is trained with cross-entropy loss, Loss = $-\Sigma\, y_i \log(\hat{y}_i)$, using the Adam optimiser with backpropagation-through-time and early stopping. The final anxiety-class probability is A = Softmax(W_h h_t + b_h), related to Low, Medium, or High anxiety using thresholds T1 and T2 (Low: A<T1; Medium: T1≤A<T2; High: A≥T2). Increased heart rate (HR) and decreased heart rate variability (HRV) are significant indicators of excitement and anxiety [15], and the LSTM tracks the speed of the occurrences of emotional changes, transitions, and different time intervals relating to stress from rising to recovery to compute anxiety intensity during virtual reality immersion [16].

D. Adaptive VR Control and Feedback

According to the level of anxiety predicted, the VR Adaptation Controller alters the complexity of the scene, speed of movement of the objects, sound level, density of crowd, time of exposure, brightness, distance of stimulus, and the difficulty in performing the tasks. It decreases the stimulation of the environment in case anxiety is high and gradually increases it in case anxiety is low, which ensures that the therapy maintains a stable emotional background. The feedback loop (physiological measurement → behavioral analysis → anxiety level prediction → adaptation of the VR to the patient → reassessment of the emotions of the patient) provides for the continuous operation of the system throughout the treatment process, which is not typical for the traditional therapy based on static models [17].

VI. Experimental Setup

The evaluation of the experiment validated the AVRET framework for anxiety prediction accuracy, emotional responsiveness, adaptive VR effectiveness, deep learning performance, personalization capability, and system reliability.

The hardware involved a VR headset, cardiovascular and GSR sensors, an eye-tracking device, motion-tracking sensors, and a GPU-based workstation for the inference process.

The software used Python, TensorFlow/Keras for LSTM-based modeling, OpenCV for behavioral analysis,

NumPy/Pandas for signal processing, Matplotlib for visualization, and Unity/Unreal Engine for VR scene rendering.

A synchronized multimodal dataset consisting of HR, HRV, GSR, eye tracking, blink, pupil, and motion signals was acquired from VR sessions with different anxiety levels. The dataset was divided into training, validation, and testing datasets. Six VR scenarios were used where the stimulus was changed depending on the predicted level of anxiety.

Using the Adam optimizer, cross-entropy loss, backpropagation through time, cross-validation, and early stopping, the LSTM model was trained on multimodal feature windows in a particular order. Performance was measured through accuracy, precision, recall, F1-score, confusion-matrix analysis, and real-time response latencies. The adaptive VR controller was tested regarding its ability to alter the complexity of the environment, density of people in the hall, exposure duration, volume of sound, speed of object movement, and visual stimuli with regard to the level of anxiety compared to a commonly used (non-adaptive) VR therapy.

The experimental process involves user checking, turning on the sensors, going through collecting the data, processing the data, studying the features, using LSTM to provide its predictions of anxiety, and monitoring the situation.

VII. Results

The evaluation of the AVRET system was conducted with respect to the parameters of anxiety prediction accuracy, adaptability, emotional responsiveness, deep learning convergence, personalization, and reliability. The research results conducted with the use of multimodal sensing and deep learning show that the reliability and adaptability level achieved is much higher than that typical of static VR therapy.

A. Anxiety Prediction Accuracy

The LSTM model has generated good predictions for anxiety from the different intensity sessions in VR, utilizing temporal-sequence processing, multimodal integration, continuous context, and its capability to adapt to emotional patterns. Table I summarizes the classification performance.

TABLE I. Evaluation Metrics

Metric	Performance
Accuracy	90.0%
Precision	94.8%
Recall	94.1%
F1-Score	94.4%
Latency	0.8 sec

B. Training Performance

Training accuracy and loss trends (Fig. 3–4) suggest a regular pattern of convergence since accuracy improved steadily again and loss decreased – thus, the LSTM learned the patterns of stress development, fluctuation, escalation, and recovery processes without overfitting.

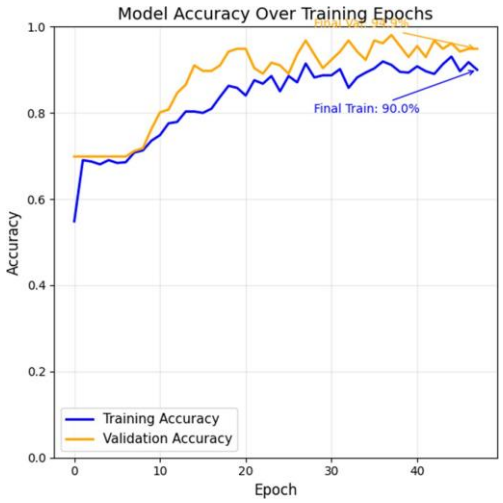

Fig. 3. Training accuracy curve of the proposed LSTM model.

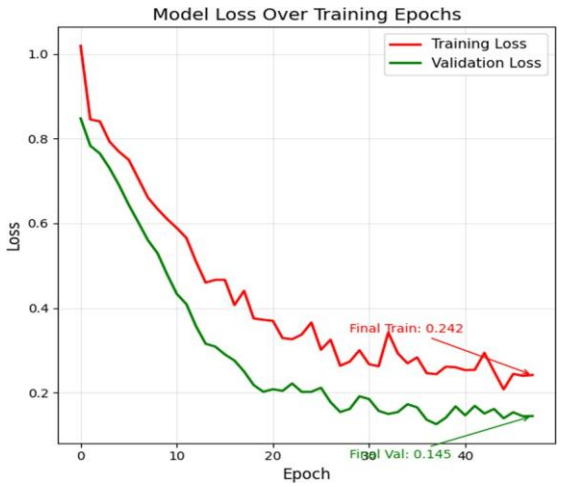

Fig. 4. Training loss curve of the proposed LSTM model.

C. Confusion Matrix Evaluation

Confusion-matrix analysis (Fig. 5–6) shows strong detection consistency with Low, Medium, and High anxiety classes with minimal misclassification, confirming the system's sensitivity to stress and emotional discomfort during VR immersion [13].

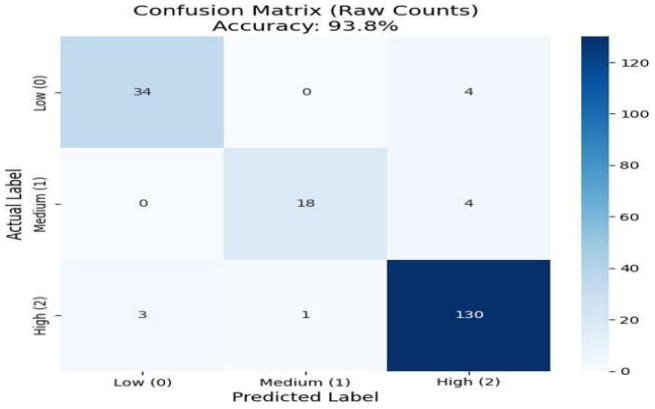

Fig. 5. Confusion matrix for anxiety classification.

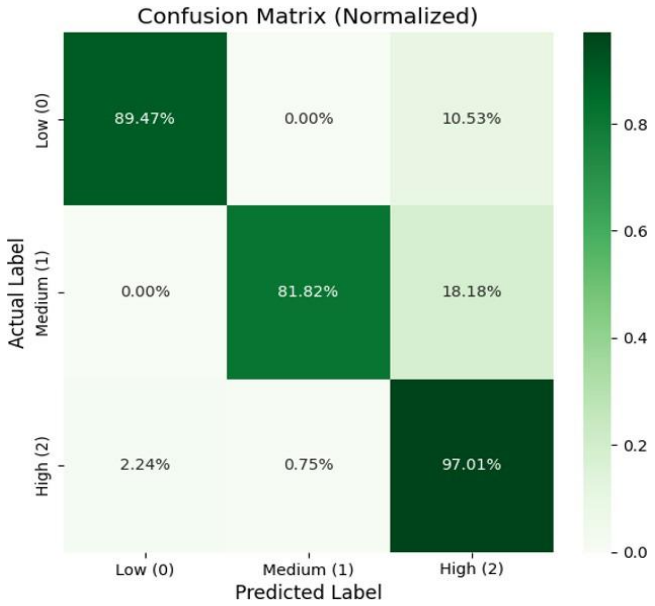

Fig. 6. Normalized confusion matrix for anxiety classification.

D. Multimodal Fusion Performance

Fusing HR, HRV, GSR, eye-tracking, and motion features substantially outperformed single-modality prediction (Table II), confirming that multimodal fusion enhances robustness and classification reliability.

TABLE II. COMPARISON OF PREDICTION APPROACHES

Method	Accuracy
Heart Rate Only	78.4%
GSR Only	80.1%
Eye Tracking Only	76.9%
Multimodal Fusion	95.2%

E. Adaptive VR and Physiological Signal Analysis

The adaptive controller successfully modulated scene complexity, exposure difficulty, sound intensity, object movement, crowd density, and environmental stimulation based on predicted anxiety [15]. Continuous multimodal monitoring (Fig. 7) shows HR rising, HRV declining, and GSR, pupil dilation, and eye blink rate varying under high-stress scenarios such as crowds, public speaking, and height exposure, showing that multimodal fusion achieves more reliable emotional representation than any single modality.

F. Adaptive VR Exposure Analysis

TABLE III. CLASSIFICATION REPORT FOR ANXIETY PREDICTION

Class	Precision	Recall	F1	Supp.
Low	91.9%	89.5%	90.7%	38
Medium	94.7%	81.8%	87.8%	22
High	94.2%	97.0%	95.6%	134

The controller continuously divided emotional state into Maintain, Reduce, or Increase Exposure based on the LSTM's predicted anxiety trajectory (Table III, Fig. 8), reducing response as anxiety increased and increasing it as the user's emotional state improved, ensuring real-time responses, dynamic personalization, continuous stress regulation, and improved emotional safety.

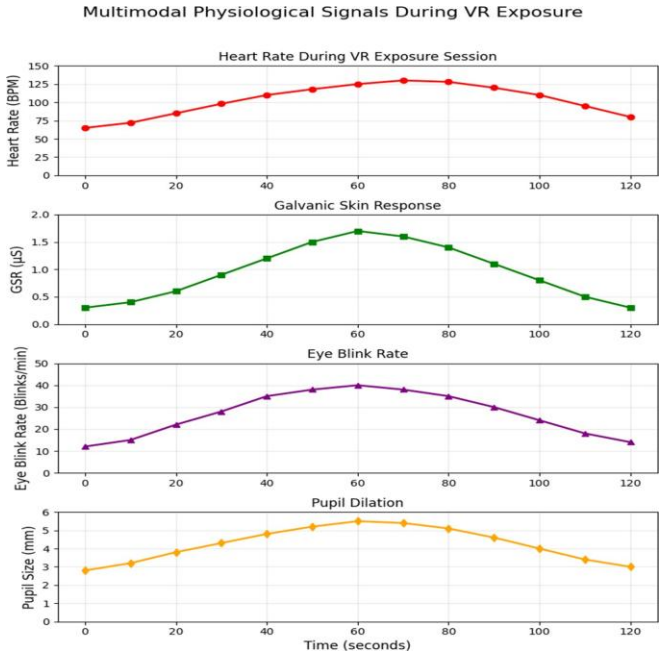

Fig. 7. Variation in multi-modal physiological signals during VR exposure.

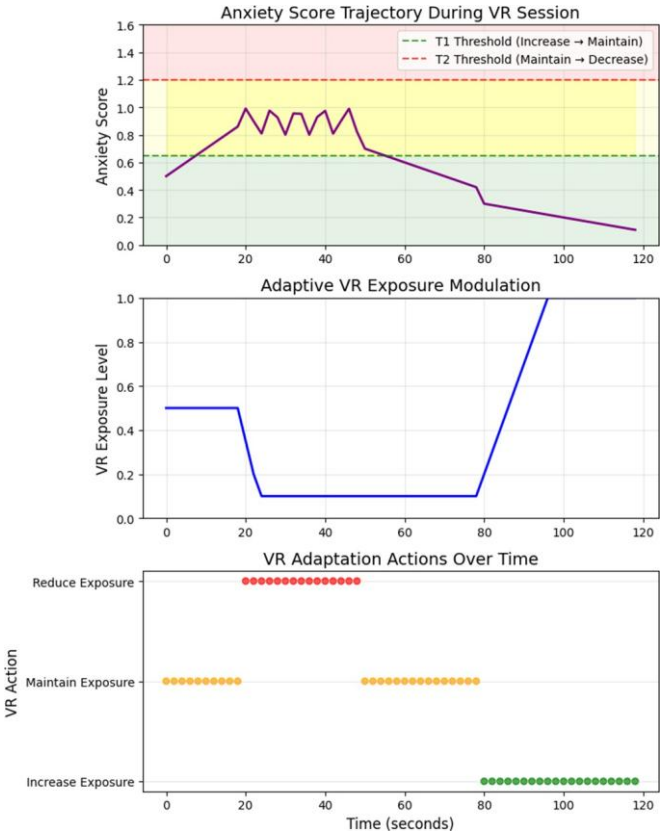

Fig. 8. Adaptive VR exposure modulation based on anxiety prediction.

G. Comparative Analysis

Table IV compares AVRET with existing approaches. Unlike traditional VRET (manual control, no adaptation) and single-modality predictors (HR-only, GSR-only, EEG-only, or eye-tracking-based models with partial or no adaptation), AVRET combines seven physiological/behavioral channels with an LSTM predictor and fully adaptive VR control, achieving markedly higher accuracy and confirming its advantage as an advanced, intelligent emotional-healthcare system.

TABLE IV. COMPARATIVE ANALYSIS

Method	Modalities	Model	RT Adapt.	VR Adapt.	Acc.
Traditional VRET	None	Manual	No	Static	Low
HR-Based	HR only	SVM	Partial	No	Moderate
GSR-Based	GSR only	RF	No	No	Moderate
EEG Emotion	EEG	CNN	Partial	No	High
Behavioral	Eye	RNN	Partial	Limited	Moderate
Proposed AVRET	Multimodal	LSTM	Yes	Full	Very High

VIII. DISCUSSION

These results support the effectiveness of multimodal physiological sensing, deep-learning-based anxiety prediction, and adaptive VR interaction for intelligent mental healthcare. This performance was driven by the LSTM architecture, which effectively learns temporal relationships among observations; unlike models that analyze each observation independently, it captured temporal dependencies in the design and resolution of anxiety, improving real-time prediction and adaptation. The adaptive VR controller used these predictions to continuously adjust exposure intensity, modifying environmental complexity, sound, and exposure duration to keep interactions emotionally balanced and avoid both overexposure and underexposure.

IX. CONCLUSION

This study proposed AVRET, a closed-loop intelligent healthcare system combining multimodal physiological sensing, behavioral analysis, LSTM-based deep learning, and adaptive VR control. The system collects HR, HRV, GSR, eye-tracking, blinking rate, pupil dilation, and other data continuously during VR therapy, processes it through a series of preprocessing, feature fusion, and deep-learning steps, and makes real-time predictions of anxiety. The experimental results demonstrate that AVRET is superior to static VR therapy in terms of prediction accuracy, emotional responsiveness, and adaptive personalization, with adaptive controller able to adjust exposure intensity based on changes in emotional state.

X. FUTURE SCOPE

This framework provides a foundation for future work to validate PA-VRET (EEG, EMG, facial expression) for richer emotional and cognitive-state recognition, and reinforcement learning or generative AI to automatically generate VR exposure environments based on patient progress. Future directions include extending AVRET to post-traumatic stress disorder, depression, workplace stress, pediatric mental healthcare, and telehealth applications using emotionally responsive VR.

***Abstract*—Traditional tourism monitoring systems rely on manual tracking and overlook dynamic factors influencing travel duration. To address this limitation, this research presents an intelligent web dashboard integrating RFID infrastructure and multimodal machine learning to assess the risk of delay in tourist activities. The project encompasses the design and physical prototyping of a Radio Frequency Identification (RFID) based checkpoint system. This prototype demonstrated functional detection of members upon entry and exit, providing an automated identification layer. To predict delays, the system processes two diverse datasets. A biometric gait dataset facilitates human speed prediction utilizing age, gender, body mass, body size, and shoe size. Simultaneously, a vehicle dataset provides environmental context through travel distance, weather ratings, traffic conditions, and vehicle classification. The study evaluates Ridge Regression, Random Forest, and Gradient Boosting Regressor algorithms for human speed prediction, while Random Forest, Gradient Boosting Regressor, and Long Short-Term Memory (LSTM) networks are utilized for vehicle speed prediction. Evaluation revealed that the Gradient Boosting Regressor achieved the lowest error metrics across both datasets. This superior model was exported and implemented into a Python Flask backend to generate live transit time estimations. The dashboard provides live visibility into member locations and implements automated missing member notifications. This allows tour organizers to respond promptly to movement irregularities without manual tracking. Overall, the results demonstrated the feasibility of the proposed automated tour group monitoring system. However, the current prototype was validated through controlled functional testing, and further multi-user and field-based evaluation is required to establish its scalability and generalizability for larger smart tourism environments.**

Keywords*—RFID; predictive analytics; multimodal machine learning; contextual data; smart tourism

I. Introduction

Tour group management often requires continuous coordination of participants during movement between destinations, especially when groups are required to gather at specific checkpoints before continuing to the next activity. Traditional approaches using manual roll calls, name lists, and verbal confirmations need direct human intervention and may result in inaccurate or delayed attendance information. Such methods are time-consuming and susceptible to human error, particularly when attendance must be repeatedly verified throughout a journey [8]. These limitations become more significant as the number of participants and checkpoints increases, since it becomes difficult to accurately verify the presence of every individual when the group moves between different locations. The absence of an automated tracking mechanism may result in members being unintentionally left behind, leading to delays, confusion, dissatisfaction, and potential safety issues [11].

Digital communication tools and mobile messaging applications can provide an alternative method for sharing attendance updates; however, these approaches still depend heavily on manual input and coordination. Group leaders may need to request individual responses from participants to confirm their arrival or departure, while participants may forget to respond, provide inaccurate information, or experience connectivity problems. Such methods also provide limited automated verification and structured historical records for confirming whether a participant has passed through a specific checkpoint. Consequently, when a member arrives late or fails to reach a designated location, group leaders may have difficulty determining whether the member is still travelling, delayed, or missing. This creates a conflict between maintaining the planned travel schedule and ensuring that all participants remain accounted for throughout the journey.

Radio Frequency Identification (RFID) provides an automated identification mechanism by assigning a unique identifier to each participant. RFID-based systems can perform automatic data capture and reduce the need for manual attendance verification. Instead of calling names or checking participant lists individually, members can present their RFID tags at designated checkpoints, allowing their attendance and checkpoint information to be recorded electronically. RFID can therefore provide structured identification records that can subsequently be transmitted to a centralized monitoring platform. Previous work has demonstrated the use of RFID with embedded hardware and cloud-based data logging to automatically record participant attendance, while RFID-based

*Corresponding author.

tracking systems can also be extended to provide centralized monitoring of member movements.

However, RFID identification alone does not provide sufficient support for tour management. A conventional RFID checkpoint system records whether a participant has been detected at a particular location but does not directly determine whether the participant is likely to arrive at the next checkpoint on time. Furthermore, when several checkpoints are operating simultaneously, the collected information needs to be synchronized and presented in a form that can be easily interpreted by tour leaders. Data synchronization and communication latency are therefore important considerations in real-time tracking systems, particularly when multiple devices are required to transmit information to a centralized platform [11]. A monitoring system must therefore not only collect RFID data but also provide timely and reliable updates to support decision-making during a journey.

Collected checkpoint records generally represent historical or status information and may require additional analysis to determine potential delays. A participant's latest recorded checkpoint alone does not indicate how long the participant will need to reach the next destination. Machine learning can complement RFID-based monitoring by learning relationships between participant characteristics, transportation conditions, and travel speed. The predicted travel performance can subsequently be used to estimate travel time and compare the expected arrival time with the checkpoint deadline. This provides predictive information that can assist group leaders in identifying participants who may be at risk of arriving late rather than relying solely on a missing-member status after the deadline has passed.

Therefore, this study proposes an RFID-Based Tour Group Tracking and Predictive Monitoring System that integrates RFID checkpoint identification, a cloud-based database, real-time web monitoring, automated missing-member notification and machine learning-based travel prediction. The RFID checkpoints record member identification at designated locations and transmit the records to a centralized database, while the dashboard synchronizes the information and presents the current member status to administrators and tour leaders in real time. The proposed architecture therefore combines physical identification, cloud data management, real-time communication, and predictive analysis within a single monitoring system.

II. Literature Review

Radio Frequency Identification (RFID) uses radio waves to identify and track tagged objects without physical contact or line-of-sight, a capability that traces back to World War II friend-or-foe radar identification [1]. A typical RFID system consists of a transponder (tag), a scanning antenna, and an emitter–receiver that together form the reader, or interrogator [2]. The reader broadcasts a radio-frequency signal to power and activate the tag, then demodulates the returned signal into digital data for downstream processing [3]. Passive high-frequency (HF) tags are preferred for short-range, contact-triggered check-in/check-out applications because they require no onboard battery, resist interference in crowded environments, and remain cost-effective for multi-checkpoint deployment, unlike ultra-high-frequency (UHF) or microwave tags who's longer read range would allow a member to pass a checkpoint undetected.

Research found that commercial group-management platforms illustrate current approaches to traveler tracking. VNFCPass assigns each traveler an NFC bracelet or badge, letting operators import participant lists, verify presence with a single tap, and manage multiple groups in parallel [4]. TourTrax combines GPS positioning with checkpoint scanning and two-way communication to provide real-time alerts and task-completion reporting for patrol-style tour operations [5]. While effective for group visibility, neither platform incorporates predictive analytics to flag members at risk of missing a scheduled deadline, a gap this study addresses. Several studies apply RFID and related IoT sensing to attendance and tracking problems. Farag and Abouelela [6] implemented a low-cost passive-RFID attendance system that logs check-in events with minimal hardware overhead. Sunder and Am [7] developed an RFID-based asset-management platform for tracking equipment across a facility. Gopinath et al. [8] proposed a real-time group-coordination system that alerts operators when a member deviates from the group. Belka et al. [9] designed a Bluetooth Low Energy (BLE) indoor-positioning system with overlap-resistant beacon placement for tourism navigation, reporting improved localisation accuracy over single-beacon layouts. Hutabarat [10] combined RFID wristbands for indoor detection with smartphone GPS for outdoor tracking and IP cameras for visual confirmation across a large recreational area, while Yadav [11] logged ESP32/RC522 RFID scans directly to Google Sheets for lightweight cloud attendance recording. Camera-based alternatives that use the MATLAB face-recognition system of Pamith et al. [12], the Flutter/Wi-Fi proximity system of Mahadik et al. [13], and the Flask–Supabase face-recognition system of Ibezim [14] achieve tag-free identification but remain sensitive to lighting, network reliability, and privacy concerns. Collectively, these works confirm RFID as a low-latency, low-power solution for controlled indoor and semi-outdoor checkpoint tracking, though few integrate a predictive layer for anticipating schedule risk.

Beyond detection, several works apply ML/DL to strengthen the predictive value and reliability of sensor data. Abbass et al. [15] used a Long Short-Term Memory (LSTM) network to predict power-system voltage stability from historical grid data, reporting high accuracy but also flagging overfitting risk on limited datasets, a consideration directly relevant to the temporal regression models developed in this study. Wang [16] proposed a CNN-based adaptive-modulation and error-correction scheme for chip-less RFID tags, showing that convolutional pattern recognition can raise signal-to-noise ratio and reduce bit-error rate compared with PSO- and 1D-CNN-based decoding, demonstrating that deep learning can improve the reliability of RFID-derived data even at the physical-signal level. In a related embedded-IoT context, Tomari et al. [17] trained YOLOv8/v9/v10 detectors to identify recyclable items on a CPU-only automated recycling machine, selecting YOLOv8-m as the best accuracy–efficiency trade-off for real-time inference on constrained hardware; the same accuracy-versus-resource trade-off suggests this project's

choice of lightweight regression models (Ridge Regression, Random Forest, Gradient Boosting) alongside LSTM for a resource-constrained Flask backend.

The reviewed literature confirms RFID as a mature, low-power solution for indoor/controlled-environment tracking [1]– [3]; the asset-management paper [4], [7] and RFID/IoT attendance systems [6]– [14] can reliably log checkpoint events. Separately, ML/DL techniques have improved prediction accuracy and signal reliability in adjacent IoT domains [15]– [17]. However, none of the reviewed group-tracking or RFID-attendance systems combine real-time checkpoint logging with a machine-learning layer that predicts individual travel risk, such as the likelihood of missing a schedule deadline, based on biometric, distance, and contextual features. This gap motivates the proposed RFID-based tour-tracking dashboard, which integrates checkpoint-level RFID logging with a two-stage ML pipeline for walking/vehicle speed and deadline-risk prediction.

III. METHODOLOGY

A. Project Design Flow

Each tour member is assigned a unique passive RFID tag. At each checkpoint, an RC522 RFID reader connected to an ESP32 detects the tag UID when the member taps the card to the reader. The ESP32 validates the received UID, filters repeated scans, associates the scan with the corresponding checkpoint, and records the timestamp. A valid scan is then transmitted through the ESP32's Wi-Fi connection to the Supabase backend in JSON format. The received RFID data is processed through the Supabase REST API and stored in the PostgreSQL database.

The React-based web dashboard retrieves and synchronizes these records using Supabase. Supabase Realtime enables new RFID events and status changes to be reflected on the dashboard without requiring manual page refreshes. The dashboard displays each member's status and checkpoint information, allowing administrators and group leaders to monitor the tour in real time. When a member fails to reach the designated checkpoint before the configured deadline, the system updates the member's status to “Missing” and generates an alert.

The system includes predictive analysis to estimate travel performance and potential delay. Machine learning models are trained using participant and transportation-related data to predict walking speed and vehicle speed. When a user requests a risk assessment, the React dashboard sends the required member and route information to the Flask backend through a RESTful API. The backend processes the input using the trained model and estimates the travel speed and corresponding travel time. The predicted travel time is compared with the predefined checkpoint deadline to determine the member's potential delay risk. The prediction results are then returned to the dashboard and presented through the Analytics Page.

B. System Architecture

The proposed system is an integrated hardware-software platform consisting of four main layers: embedded hardware, cloud database, frontend application and machine learning backend, as shown in Fig. 1. The overall architecture enables RFID data collected at physical checkpoints to be transmitted to the cloud database, synchronized with the web dashboard in real time, and used for travel-time and delay-risk prediction.

The embedded hardware layer collects RFID checkpoint events, while the cloud database layer stores and manages system data. The frontend application provides interfaces for member management, real-time monitoring, route configuration, and analytics. The machine learning backend processes prediction requests from the frontend and provides travel-time and delay-risk results. These layers work together to provide an automated system for monitoring tour group movements and identifying potential delays.

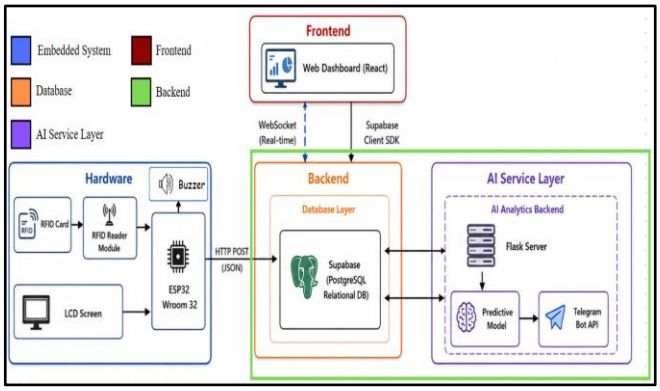

Fig. 1. Block diagram of the integrated RFID-based tracking and monitoring system for tour group members.

C. RFID Checkpoint Hardware Implementation

The RFID checkpoint was designed as a portable identification station that can be deployed at different locations during a group journey. The ESP32-WROOM-32 was selected as the central microcontroller because it provides integrated Wi-Fi connectivity and supports the communication interfaces required to connect the RFID reader and display. The RC522 reader was selected as the HF RFID reader, while passive RFID cards were used as member identification tags. The use of passive tags eliminates the requirement for individual tag batteries and is therefore suitable for repeated use by tour participants.

The RC522 communicates with the ESP32 through the SPI interface. The RFID reader is connected to the ESP32 through the corresponding power, reset, clock, master-in/slave-out, master-out/slave-in, and chip-select lines. An I²C LCD is connected separately to provide visual feedback, while the buzzer is connected to a GPIO output for audible confirmation. The hardware arrangement allows the ESP32 to simultaneously communicate with the RFID reader and peripheral feedback devices.

Fig. 2 shows the flowchart of mode operations at the checkpoint. Two operating modes are implemented at the RFID checkpoint: the registration mode and tracking mode. During registration, an administrator scans an RFID card and associates its UID with the selected participant profile. During tracking, the system verifies whether the scanned UID has been registered. For a valid UID, the system records the participant's identity, checkpoint, and timestamp and provides successful-

scan feedback through the LCD and buzzer. The RFID scan record is subsequently transmitted to the cloud database for further processing.

This approach allows the physical checkpoint to function independently as a data acquisition device while the database and web application handle storage, visualization, and higher-level analysis.

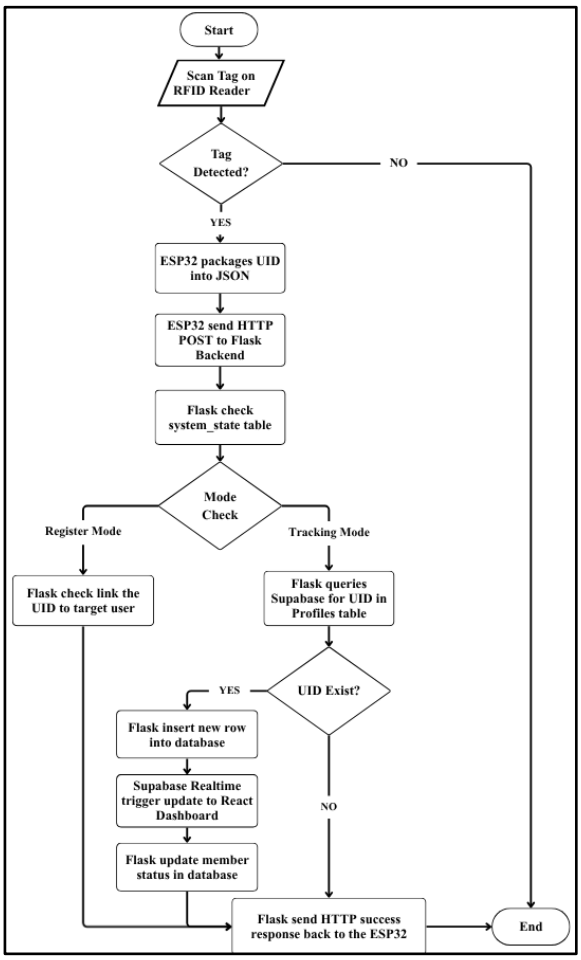

Fig. 2. Flowchart of track and register mode at checkpoint.

D. Cloud Database and Real-Time Monitoring

The Supabase PostgreSQL database serves as the central storage layer for the system. The database contains structured information covering participant profiles, RFID identifiers, travel groups, checkpoints, travel sessions, and system states. RFID scan records contain the information required to determine a participant's most recent confirmed checkpoint and movement history.

After an RFID scan is successfully processed by the ESP32, the scan record is inserted into the database through an HTTP request. The database update then becomes the source event for the real-time monitoring system. Instead of requiring the dashboard to repeatedly reload the database, Supabase Realtime is used to detect changes to subscribed tables and propagate them to connected clients.

The React dashboard maintains subscriptions to relevant database changes. When a new RFID record is inserted, or an existing participant status is updated, the corresponding dashboard components refresh their displayed information. This allows the current checkpoint, member status, and group attendance information to be presented without requiring manual page refreshes.

The dashboard also provides administrative functions for creating and modifying members, groups, checkpoints, and routes. Administrators can configure checkpoint locations, assign members to groups, and create a designated gathering or exit checkpoint. Group leaders can use the monitoring interface to observe participant status and identify members who have not reached the required checkpoint.

E. Real-Time Communication and Missing-Member Detection

Two communication mechanisms were considered for synchronizing checkpoint changes with the dashboard which are HTTP polling and WebSocket communication. In the polling approach, the client periodically sends HTTP requests to check whether new data is available. The system used a three-second polling interval during performance evaluation. Although polling is straightforward to implement, updates can remain undetected until the next polling cycle, and shorter polling intervals increase the number of requests and network traffic.

The proposed system therefore uses Supabase Realtime WebSocket communication for the deployed monitoring function. Supabase Realtime uses PostgreSQL logical replication to detect subscribed INSERT and UPDATE operations. When a relevant database record changes, the update is pushed to connected clients through a persistent WebSocket connection. This event-driven approach is suitable for RFID checkpoint monitoring because scan events occur irregularly and may require immediate notification.

A missing-member detection mechanism is implemented using the checkpoint deadline defined for a travel route. When the system determines that a participant has not reached the designated checkpoint within the required time, the participant status can be updated to “Missing”. The status is displayed on the dashboard, and a notification can be generated for the administrator. The notification provides information such as the participant's name, group and contact information to support follow-up action.

F. Route Management and Travel-Time Prediction

The system includes a route-management module that allows administrators or group leaders to define a sequence of checkpoints before a journey begins. Each route is divided into segments, with each segment containing a starting checkpoint, destination checkpoint, and transportation mode. The transportation modes supported include walking, vehicle, and bus.

After a route has been created, the user can select a participant and initiate a risk prediction. The system sends the participant's profile information, route information, checkpoint sequence, and transportation modes to the Flask prediction

backend. The backend calculates the expected travel duration for each route segment according to its assigned transportation mode. The predicted segment durations are then combined to obtain the estimated total journey time.

For a designated exit or gathering checkpoint, the estimated arrival time is compared with the configured deadline. The difference between the predicted arrival time and the required arrival time is used to determine whether the participant is likely to be late. The resulting prediction is returned to the React dashboard, where the estimated journey duration, remaining time, risk percentage, route status, and segment-level prediction are displayed.

This prediction process allows the system to provide information before and during a journey rather than relying solely on historical RFID records. When a new RFID scan is received during the journey, the participant's latest confirmed checkpoint can be used to update the prediction according to the remaining route. The following equations define the estimated travel time and the corresponding deadline-utilization ratio.

$$T_{estimated} = \frac{D}{V_{predicted}} \quad (1)$$

where:

- D = remaining travel distance
- $V_{predicted}$ = predicted walking or vehicle speed
- $T_{estimated}$ = estimated time required to reach the destination/checkpoint

and

$$R = \frac{Tneeded}{T_{remaining}} \times 100\ \% \quad (2)$$

where:

$T_{remaining}$= time remaining until the relevant deadline

R = risk-utilization ratio, expressed as a percentage

G. Machine Learning Model Development

Fig. 3 shows the pipeline of the machine learning process. The machine learning component was developed to estimate participant travel speed and support delay-risk assessment. The development process consisted of data collection, preprocessing, dataset splitting, model training, hyperparameter tuning, performance evaluation, model selection and deployment. The full pipeline follows the process of preparing the datasets, training multiple candidate models, evaluating their predictive performance, and deploying the best-performing model into the integrated tracking system.

1) Walking speed prediction: The walking-speed dataset contains 1,274 participant records of participant characteristics including age, gender, body mass, body size, shoe size, and measured gait speed. The dataset was cleaned before model development by removing duplicated records, standardizing attribute names, encoding categorical gender information, and handling missing values. Missing values were processed using a two-stage imputation approach based on participant grouping.

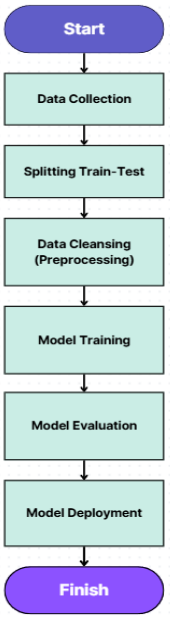

Fig. 3. Pipeline of machine learning process.

The processed dataset was divided into training and testing subsets using a random 80:20 train-test split, resulting in 1,019 records for training and 255 records for testing. Feature scaling was applied to the numerical inputs where required, with the scaler fitted using the training data to avoid information leakage into the testing set.

Three regression algorithms were evaluated using Ridge Regression, Random Forest Regression, and Gradient Boosting Regression. These models were selected to compare linear regression with ensemble tree-based approaches capable of representing nonlinear relationships between participant characteristics and walking speed.

2) Vehicle speed prediction: A separate vehicle travel dataset containing 146 trip records was used for vehicle-speed prediction. Unlike the human gait dataset, the vehicle dataset consists of only 146 trip records. A random 80:20 train-test split was initially performed, resulting in 116 records for training and 30 records for testing. Due to the relatively small number of training samples, a data augmentation technique was subsequently applied to expand the training set and provide additional samples for model development. The testing set was isolated before augmentation and remained completely untouched throughout the training process. The input features include travel distance, traffic condition, weather condition, vehicle type, day, and travel hour. These variables were selected to represent the environmental and temporal factors that may influence vehicle travel speed.

The dataset was preprocessed before training and divided into training and testing subsets. Three models were evaluated for vehicle-speed prediction using Random Forest Regression, Gradient Boosting Regression, and Long Short-Term Memory

(LSTM). Random Forest and Gradient Boosting were used as ensemble regression approaches, while LSTM was included to evaluate whether a recurrent neural network could capture patterns in the available travel data.

The models were evaluated using regression performance metrics, particularly MAE and the model achieved the lowest prediction error and was subsequently selected as the deployed vehicle-speed model. The selected model was serialized and integrated into the Flask backend together with the walking-speed model.

3) Evaluation metrics: In machine and deep learning, selecting appropriate evaluation metrics is important to measure the predictive accuracy of a trained model and to make fair comparisons across different algorithms. For regression tasks where the output is a continuous numerical value, three widely adopted metrics are Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and the coefficient of determination (R^2). Below are the equations used [18]:

a) Mean absolute error: MAE calculates the average errors between predicted and actual values without considering their direction in the dataset [18].

$$\text{MAE} = \frac{1}{n}\sum_{i=1}^{N} |y_i - \hat{y}_i| \quad (3)$$

b) Root mean squared error: RMSE is the square root of MSE (Mean Squared Error); it measures on how far the variation in the dependent variable is explained by the independent variables. Lower RMSE indicates less error.

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (4)$$

c) R-squared: R-squared is also known as the coefficient of determination which measures how well a model fits the data and the power to predict future outcomes. The ranges are capping from 0 to 1, where 1 indicates a perfect fit of the model to the data.

$$R^2 = 1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y})^2} \quad (5)$$

4) Prediction deployment: After evaluation, the selected models were exported using Joblib and stored in the Flask backend, avoiding the need for retraining during each journey. When a prediction is requested, the React dashboard sends the participant and route data to the Flask API. The backend selects the appropriate model based on transportation mode, processes the data and predicts travel speed. The predicted speed and route distance are then used to estimate travel time, calculate total journey duration, and determine delay risk against the checkpoint deadline.

This architecture separates data acquisition, storage, user interaction and prediction, allowing the RFID hardware to remain lightweight while machine learning processing is handled by the backend. It also allows models to be updated independently without modifying the physical RFID system.

IV. Result and Discussion

A. Result from RFID Reader

Fig. 4 shows the circuit setup of the proposed work. When an RFID tag is detected by the reader, the buzzer beside the ESP32 microcontroller will sounds to notify the user that the scan is detected, along with visual feedback on the LCD screen displaying "Scanned" to confirm the scanning action was successful; the status is updated to the current checkpoint.

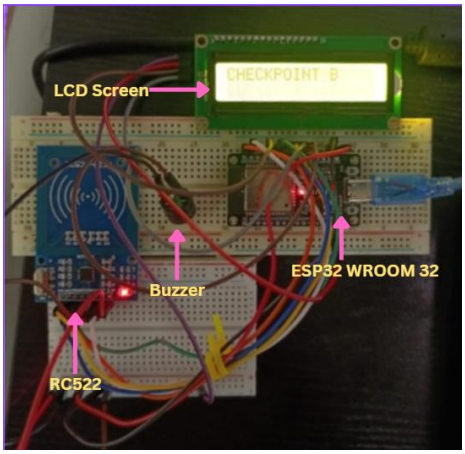

Fig. 4. Circuit setup.

Table I shows the scan detection test of the proposed work. From the results, the RFID reader can read the tag at a maximum of 4 cm from the reader. When the card tag is held further away from the reader, the card is not detected; no scan is triggered until the card enters the range of the reader scanning field. This is because the operating frequency of the RFID MFRC522 reader operates at high frequency of 13.56 MHz, which relies on inductive coupling for communication between the reader and the passive RFID tag. The magnetic field strength decreases rapidly as the distance increases, resulting in a relatively short operating range. Because passive RFID tags have no internal power source, they rely entirely on the reader's magnetic field to induce enough voltage in the tag antenna to power the chip.

TABLE I. Scan Detection Test

Test Case	Input	Expected Result	Pass/Fail
Card within range	RFID card held 1cm from reader	UID detected	Pass
Card at max range	RFID card held 2 cm from reader	UID detected	Pass
Card at max range	RFID card held 3 cm from reader	UID detected	Pass
Card at max range	RFID card held 4 cm from reader	UID detected	Pass
Card at max range	RFID card held 5 cm from reader	UID detected	Fail

As the magnetic field weakens rapidly with distance, the tag cannot retrieve sufficient energy to operate or send back its UID. This principle follows the equation of the inverse-cube law, where:

$$H \text{ is} \propto \frac{1}{d^3} \quad (4)$$

H= magnetic field strength

d= distance from the reader antenna

The greater the distance from the antenna, the weaker the magnetic field strength.

1) Tracking mode: Fig. 5 shows the serial monitor output when a member's RFID card was scanned at Checkpoint A. The ESP32 successfully initialized the RC522 RFID reader and established a Wi-Fi connection with the Supabase backend before entering tracking mode. When the RFID card was detected, the RC522 captured the card UID, and the ESP32 verified it against the registered member records in Supabase. The scanned UID was successfully matched to the registered member, CCY, and the system recorded the member as checked in at Checkpoint A. The ESP32 then updated the corresponding movement record in the Supabase database with the checkpoint and timestamp information.

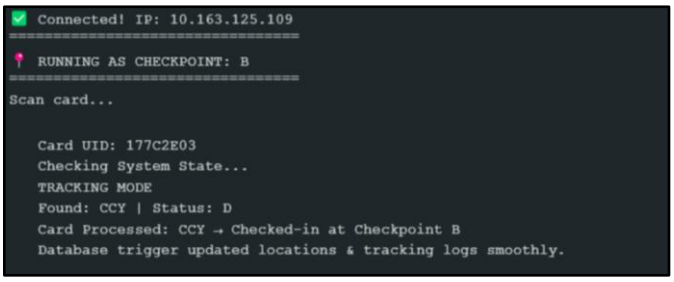

Fig. 5. Arduino serial monitor output during tracking scan.

The database update was propagated through Supabase Realtime WebSocket, allowing the React dashboard to update the member's status immediately. As shown in Fig. 6, the member's previous checkpoint status was changed from Checkpoint D (Queensbay Mall) to Checkpoint A (Universiti Malaysia Perlis), confirming successful RFID detection, database update, and real-time dashboard synchronization.

Fig. 6. Member status update to Checkpoint B in web dashboard.

2) Register mode: As shown in Fig. 7, an administrator can register or update a member's RFID card by entering the UID manually or selecting the Scan button. The system switches to REGISTER MODE, where the ESP32 captures the RFID UID and links it to the selected member's profile in the Supabase Profiles table. After successful registration, the system returns to TRACKING MODE, while the dashboard changes from "Waiting for Scan" to "Card Scanned", confirming successful registration.

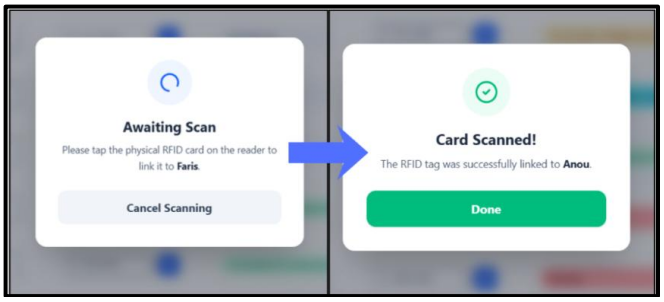

Fig. 7. After the card is scanned in the web dashboard.

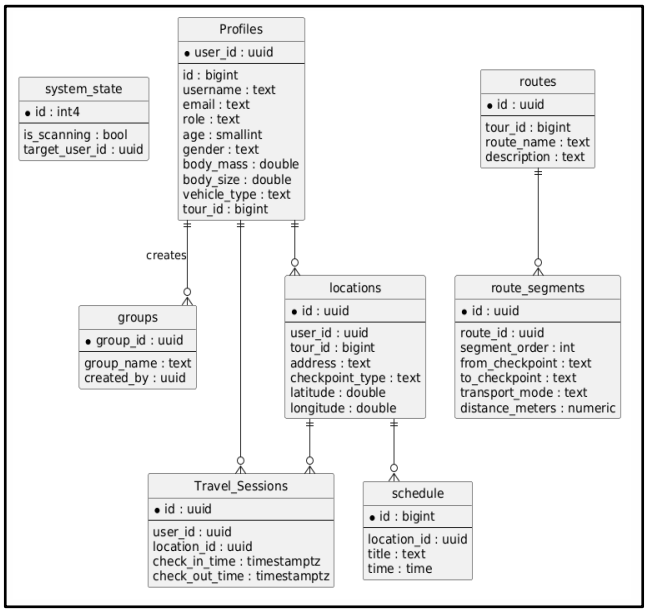

Fig. 8. Entity relationship diagram of RFID-based travel group tracking and monitoring system.

Fig. 8 shows the Entity Relationship Diagram (ERD) of the RFID-based Travel Group Tracking and Monitoring System. The Profiles table acts as the central entity, storing member information such as biometric data, RFID tag number and vehicle type. It is linked to the Groups, Travel_Session and Locations tables for member management, travel status, and location tracking. The Locations table records checkpoint scans, coordinates, timestamps and calculated distances to the exit checkpoint, supporting the Analytics dashboard and risk prediction. The Checkpoints table stores the location and exit status of each checkpoint. The Routes table defines each route, while Route_Segments stores its sequence, checkpoints, transportation mode, and travel distance. The Schedule table is linked to locations and stores planned activities and expected arrival times, which support system monitoring and risk prediction.

B. Supabase Table Relationship Design

C. Web Dashboard Test Result

Tables II, III, IV, and V show the member, group, and route analytics management page tests, respectively.

TABLE II. MEMBER MANAGEMENT PAGE TEST

Feature Tested	Expected Behaviour	Observed Behaviour	Result
RFID tag registration via scan button	New card UID links to selected member profile	Card UID written to database table and user interface shows output.	Pass
Manual RFID UID entry	Admin can type UID directly without scanning	UID saved to database on submit	Pass
Status edits by admin	Admin changes member status	Status updated in Supabase and UI refreshed	Pass
Status edits attempt by member role	Edit controls should be disabled for non-admin users	Edit fields not interactive for member role	Pass
Role toggle (Member to Admin)	Clicking action icon switches user role	Role updated and shield icon highlighted in red	Pass
Real-time update from external change	Table reflects changes made by another admin session	New status appeared without manual refresh	Pass

TABLE III. GROUP MANAGEMENT PAGE TEST

Feature Tested	Expected Behaviour	Observed Behaviour	Result
Create new group	New team card appears after naming	Team created and visible immediately	Pass
Assigning member to group	Selected member added to team list	Members appeared under correct team with inherited transport mode	Pass
Removed from group	Member unassigned and returned to pool	Member removed from team list instantly	Pass
Change group transport mode	All members in group update to new mode	Transport mode updated in bulk across all members	Pass
Rename group	Group name updates across all associated records	Name changed and reflected in member records	Pass

TABLE IV. ROUTE MANAGEMENT PAGE TEST

Feature Tested	Expected Behaviour	Observed Behaviour	Result
Create new route	Route saved with defined checkpoint sequence	Route appeared in route list with correct segments	Pass
Delete route	Route removed from list permanently	Route no longer appeared after deletion	Pass
Run risk prediction for member	Predicted travel time and risk percentage displayed	Segment breakdown and total journey time shown correctly	Pass
Segment transport mode variation	Each segment uses its assigned transport mode for prediction	Different predicted times shown per transport mode per segment	Pass

Across all four dashboard pages, Member Management, Group Management, Route Management, and Analytics, all test cases passed; Objective 2, which is functional webpages is achieved. Role-based access control, member and transport-mode updates, route-specific risk predictions, and transport-mode-based analytics were successfully verified. The Analytics page also correctly identified delayed members and triggered missing-member notifications, fulfilling the automated alert requirement.

TABLE V. ANALYTICS PAGES TEST

Feature Tested	Expected Behaviour	Observed Behaviour	Result
Display walking mode predictions	Members using walking mode show predicted time and risk	Risk percentages and time needed displayed per member	Pass
Display vehicle mode predictions	Members using vehicle mode show predicted speed and risk	Risk percentages and predicted speed displayed per member	Pass
Display bus mode predictions	Members using bus mode show predicted time and risk	Risk percentages displayed correctly for bus group	Pass
Toggle between transport types	Updates displayed member list and predictions	Member list and predictions changed per selected mode	Pass
Delay risk alert trigger	Member exceeding deadline threshold flagged as delay risk	Red highlight and extra time needed shown for at-risk member	Pass
Real-time prediction update	Predictions update when a new RFID scan occurs	Risk values refreshed after simulated new scan event	Pass

D. Result from Machine Learning

Fig. 9 shows risk prediction feature estimates whether a selected member can reach the exit checkpoint before the deadline. The user selects the route segments, transportation mode, and member before running the prediction. The system then uses trained machine learning models to estimate travel time for each segment based on the member's profile and selected transport mode. The results show the total travel time, remaining time, delay risk percentage, and status (On Track or Delay Risk). A segment breakdown also shows the predicted travel time and distance for each segment, helping administrators identify potential delays and adjust the route or transportation mode before the trip.

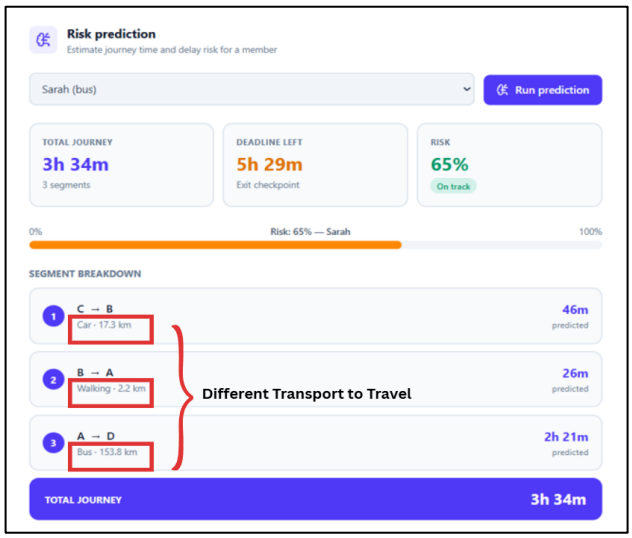

Fig. 9. Route time prediction.

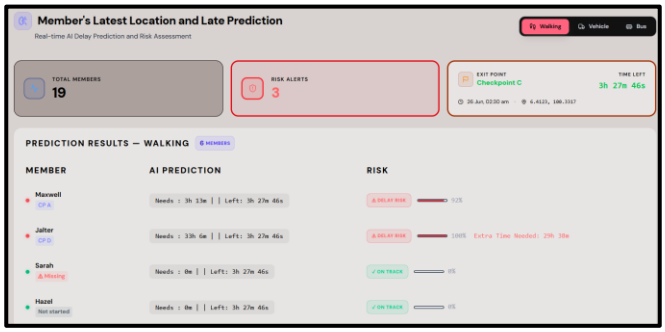

Fig. 10. Analytics page for transport using walking type member.

The Analytics Page integrates the trained machine learning models to provide real-time travel predictions. The system retrieves member biometric data, current location and remaining time from Supabase and sends them to the Flask backend for prediction. The dashboard displays each member's location status, predicted travel time, remaining time, and delay risk percentage using the formula:

$$\text{Risk} = (\text{Predicted Time Needed} \div \text{Time Remaining}) \times 100$$

Members predicted to exceed the deadline are marked as "DELAY RISK" and display the estimated extra time required. For example, in Fig. 10, three members are predicted to be late. The system updates predictions when new RFID scans or checkpoint deadline changes occur, allowing administrators to monitor members and act against potential delays.

TABLE VI. COMPARISON OF MODEL PERFORMANCE ON THE HUMAN DATASET

Metric	Random Forest	Gradient Boosting	Ridge Regression
R^2	0.9307	0.9313	0.0417
Mean Absolute Error (m/s)	0.0235 approx. (0.08 km/h)	0.0234 approx. (0.08 km/h)	0.0908 approx. (0.33 km/h)
Root Mean Square Error	0.0303	0.0302	0.1127
Training Time (s)	37.44	15.05	0.2003

As depicted in Table VI, Random Forest and Gradient Boosting achieved strong performance, with R^2 above 0.93, while Ridge Regression performed poorly with an R^2 of 0.0417 due to its inability to capture the non-linear relationship in gait speed.

Gradient Boosting achieved the lowest MAE of 0.0234 m/s and RMSE of 0.0302 m/s, closely matching Random Forest. It was also faster to train (15.05s vs. 37.44s), making it the preferred model. The low prediction error corresponds to approximately ±1.3 seconds of travel-time uncertainty per 100 m, indicating sufficient accuracy for reliable delay-risk assessment.

From the evaluation results, Gradient Boosting Regressor achieved the best result among these 3 models; hence, it is selected and downloaded to use as the model for the walking speed predictions and further implemented in the Flask backend later. The selected model and its scaler were then exported as a .pkl file and integrated into the Flask backend to make real-time walking speed prediction within the prediction system.

TABLE VII. COMPARISON OF MODEL PERFORMANCE ON THE VEHICLE DATASET

Metric	Random Forest	Gradient Boosting	LSTM
R^2	0.5177	0.6222	0.0296
Mean Absolute Error (km/h)	5.0695	5.0152	6.9337
Root Mean Square Error (km/s)	6.9913	6.1875	9.9186
Total Train Time (s)	26.25	23.42	8.95

As shown in Table VII, Gradient Boosting achieved the best performance, with the highest R^2 of 0.6222, lowest MAE of 5.0152 km/h, and lowest RMSE of 6.1875 km/h. Random Forest performed slightly worse, while LSTM had the lowest accuracy with an R^2 of 0.0296. Although LSTM had the shortest training time, Gradient Boosting was selected as the final model due to its better prediction accuracy and fit to the study situation.

The Gradient Boosting MAE represents approximately 32.09% relative error, which is higher than the walking-speed model due to factors such as traffic, road conditions, and driver behaviour.

Based on the evaluation of Random Forest, Gradient Boosting, and LSTM, the Gradient Boosting model was selected due to its lowest MAE and RMSE. The final model and scaler were saved as .pkl files and integrated into the Flask backend for speed estimation.

V. CONCLUSION

All three project objectives were successfully achieved. The RFID-based prototype successfully detected and registered tour group members at designated checkpoints, fulfilling the first objective. The second objective was achieved through the development of a real-time web dashboard that monitors member locations and provides automated missing-member alerts. The third objective was fulfilled through the training and evaluation of machine learning models for walking and vehicle speed prediction, with Gradient Boosting selected for its superior performance and integrated into the Flask backend. Overall, the integration of RFID, IoT devices, cloud databases and machine learning presented the feasibility of an automated tour group monitoring system. However, limitations such as the short reading range of HF RFID, Internet dependency, and limited dataset size remain challenges for large-scale deployment.

Future work will focus on upgrading the HF RFID module to a UHF long-range reader to achieve automatic scanning without requiring users to present their cards close to the reader. The system can also be improved by implementing stronger security and a multi-trip management structure. Finally, collecting larger and more diverse datasets across different locations, transportation modes and traffic conditions will improve the accuracy and generalizability of the machine learning models.

ACKNOWLEDGMENT

The authors would like to express their sincere gratitude to Universiti Malaysia Perlis (UniMAP) for providing the necessary facilities and funding to support this work.

Design and Formalization of a Distributed Intelligent Edge-Fog-Cloud Architecture for Industry 4.0 Systems

Hafsa AMALIK*, Hicham MEDROMI
Research Laboratory in Networks-Computer Science-Telecommunications & Multimedia (RITM)-System Architecture Team (EAS), National High School of Electricity and Mechanics (ENSEM), Hassan II University, Casablanca, Morocco

***Abstract*—Industry 4.0 systems increasingly require distributed decision-making capabilities to manage heterogeneous resources, large volumes of data, and time-sensitive operational constraints. This study proposes a distributed intelligent Edge-Fog-Cloud architecture combining a structural seven-component intelligent-entity model, a distributed cognition mechanism based on the Perceive, Analyze, Decide, and Act (PADA) cycle, hierarchical coordination, and graceful degradation. The contribution lies in the consistent integration of these mechanisms across Edge, Fog, and Cloud decision levels. The framework is illustrated through a proposed deployment scenario derived from the OCP Benguerir phosphate-processing facilities. The present study provides an architectural and qualitative analysis; it does not report physical deployment, prototype, simulation, or quantitative performance evaluation. Responsiveness, scalability, availability, and resilience are therefore treated as design objectives that require future empirical validation.**

I. INTRODUCTION

Industry 4.0 is reshaping industrial systems through the integration of Cyber-Physical Systems, Industrial Internet of Things technologies, and intelligent data-driven services [1], [2]. Modern industrial environments are now highly connected. They generate large volumes of operational data and demand decisions that are both faster and more adaptive. Traditional centralized architectures struggle to meet these requirements, particularly in terms of responsiveness, scalability, and resilience [3], [4].

Research on the digital transformation of industry has followed three main directions. The first builds on the convergence of Cyber-Physical Systems (CPS), the Industrial Internet of Things (IIoT), and cloud services [1], [2]. By tightly coupling physical assets with computational and communication capabilities, CPS provide a solid foundation for smart manufacturing. They enable real-time monitoring, process automation, and adaptive control [5], [6]. The later integration of cloud platforms and digital twin technologies extended these capabilities toward global supervision and long-term optimization [7], [8].

The second direction emerged as industrial environments grew more complex. Multi-Agent Systems (MAS) appeared as a natural answer to the limitations of centralized control. They offer distributed decision-making and cooperative behavior among heterogeneous resources [9], [10]. Despite this flexibility, their integration with IIoT infrastructures and their ability to sustain consistent multi-level coordination remain limited at industrial scale [10], [11].

These limitations motivated a third direction, based on Edge-Fog-Cloud architectures. Such architectures distribute computation across several layers. Processing is brought closer to physical assets, which reduces latency and improves scalability [3], [4], [12]. Their effectiveness has been demonstrated in predictive maintenance and smart manufacturing applications [8], [13]. However, most of these solutions remain centered on communication and data processing infrastructure. The organization of distributed intelligence, the formal representation of intelligent entities, and the integration of resilience mechanisms are rarely treated as first-class architectural concerns [5], [7]. This gap motivates the framework proposed in this work. A detailed positioning of the proposed architecture with respect to these approaches is provided in Section IV.

Recent studies have extended this continuum through collaborative task offloading, cloud-fog-edge reference frameworks, implementation-oriented industrial architectures, resilience analyses, and quantitative performance models [14], [15], [16], [17], [18]. These contributions confirm the importance of distributing computation and coordination across heterogeneous tiers. Nevertheless, explicit entity abstractions, cognition cycles, decision subsidiarity, and graceful degradation are not always integrated within a single architectural representation, which motivates the structural framework developed in this study.

This study proposes a distributed intelligent architecture built on four pillars: a formal model of intelligent entities, a distributed cognition mechanism based on the PADA cycle (Perceive, Analyze, Decide, Act), hierarchical coordination, and resilience through graceful degradation. The applicability of the framework is illustrated through a proposed deployment scenario derived from the OCP Benguerir phosphate-processing facilities. No physical deployment or quantitative validation is claimed.

The main contributions are: 1) a multi-layer Edge-Fog-Cloud architecture where intelligence is an intrinsic component; 2) a formal seven-component entity model; 3) a distributed PADA cognition model; 4) hierarchical coordination and

*Corresponding author.

resilience mechanisms; and 5) an industrially grounded deployment scenario based on the OCP Benguerir phosphate-processing facilities.

The remainder of the study is organized as follows. Section II presents the proposed architecture. Section III presents the industrial case study and the proposed deployment scenario. Section IV provides a comparative analysis with existing approaches. Section V discusses the findings, and Section VI concludes the study.

II. Proposed Distributed Intelligent Architecture

A. Design Principles

The proposed architecture is built around three design principles that address the limitations of existing Industry 4.0 frameworks [3], [4], [5].

The first principle is distributed responsibility, where perception, analysis, decision-making, and action capabilities are distributed among autonomous entities across all system levels. This organization improves responsiveness and reduces dependence on centralized infrastructures, which are increasingly unable to meet the real-time requirements of modern industrial environments [11].

The second principle is multi-level coordination, whereby local decisions remain aligned with broader operational objectives through structured coordination mechanisms. This approach preserves the flexibility required for local autonomy while ensuring consistency with system-wide goals [5].

The third principle is interoperability and modularity, through which the framework relies on standardized communication protocols and a modular deployment strategy. This facilitates progressive integration within heterogeneous industrial environments that typically combine legacy equipment with modern digital technologies [12].

Based on these principles, the architecture is organized into three complementary layers, namely Edge, Fog, and Cloud, which together provide the foundation for a distributed intelligent system capable of combining local responsiveness, coordinated decision-making, and operational resilience within a unified Industry 4.0 framework.

B. Multi-Level Edge-Fog-Cloud Architecture

The architecture proposed in this work adopts a multi-level Edge-Fog-Cloud organization designed to distribute intelligence according to the temporal and operational requirements of industrial decision-making. As illustrated in Fig. 1, the architecture is structured around three complementary layers that collectively support perception, analysis, coordination, and optimization functions across the industrial system.

This organization is motivated by the observation that industrial decisions differ significantly in terms of urgency, scope, and computational complexity. Certain events require immediate reactions at the equipment level, while others depend on a broader operational context or long-term analysis. A centralized architecture is often unable to efficiently address these heterogeneous requirements because all information must be transmitted to a common processing point before decisions can be made. In contrast, the proposed architecture distributes responsibilities across multiple decision horizons while maintaining global system coherence [3], [5].

The Edge layer represents the operational level of the architecture. It is directly connected to physical assets and industrial equipment through sensors and actuators. At this level, intelligent entities continuously monitor operational parameters such as vibration, current consumption, pressure, flow rate, conveyor speed, and product quality indicators. The primary objective of the Edge layer is to ensure real-time responsiveness by processing information locally and executing immediate corrective actions whenever necessary. This capability is particularly important in industrial environments where delays of only a few seconds may lead to equipment damage, production losses, or safety risks [3], [19].

The Fog layer acts as an intermediate coordination level between local operations and global supervision. Rather than focusing on individual equipment, Fog nodes maintain a contextual view of an entire production area. They aggregate information originating from multiple Edge entities, correlate events, execute predictive analytics functions, and coordinate operational decisions within their respective zones. In the proposed deployment scenario, three Fog nodes are mapped to the three major phases of the OCP Benguerir production line: destoning, screening, and loading. This organization allows operational decisions to benefit from a broader context while preserving the responsiveness required by industrial processes [4].

The Cloud layer provides strategic and system-wide intelligence. It is responsible for global supervision, long-term optimization, model management, and knowledge extraction from historical operational data. Unlike Edge and Fog layers, which primarily focus on immediate and medium-term decisions, the Cloud layer operates over longer time horizons and supports continuous improvement of the industrial system. It also coordinates distributed learning processes and maintains a global representation of production activities, equipment conditions, and operational performance [1].

A key characteristic of the proposed architecture is the existence of bidirectional information flows between the three layers. Operational data generated at the Edge level are progressively aggregated and contextualized as they move toward the Fog and Cloud layers. Conversely, optimization policies, model updates, and strategic decisions generated at higher levels are propagated downward and adapted to local operational conditions. This continuous exchange of information enables the architecture to combine local autonomy with global coordination.

Unlike many existing Edge-Fog-Cloud solutions that focus primarily on data processing infrastructure, the proposed architecture explicitly integrates decision-making, coordination, and resilience mechanisms within the architectural model itself. This approach transforms the architecture from a simple communication hierarchy into a distributed intelligent system capable of supporting complex Industry 4.0 applications while maintaining operational continuity and scalability.

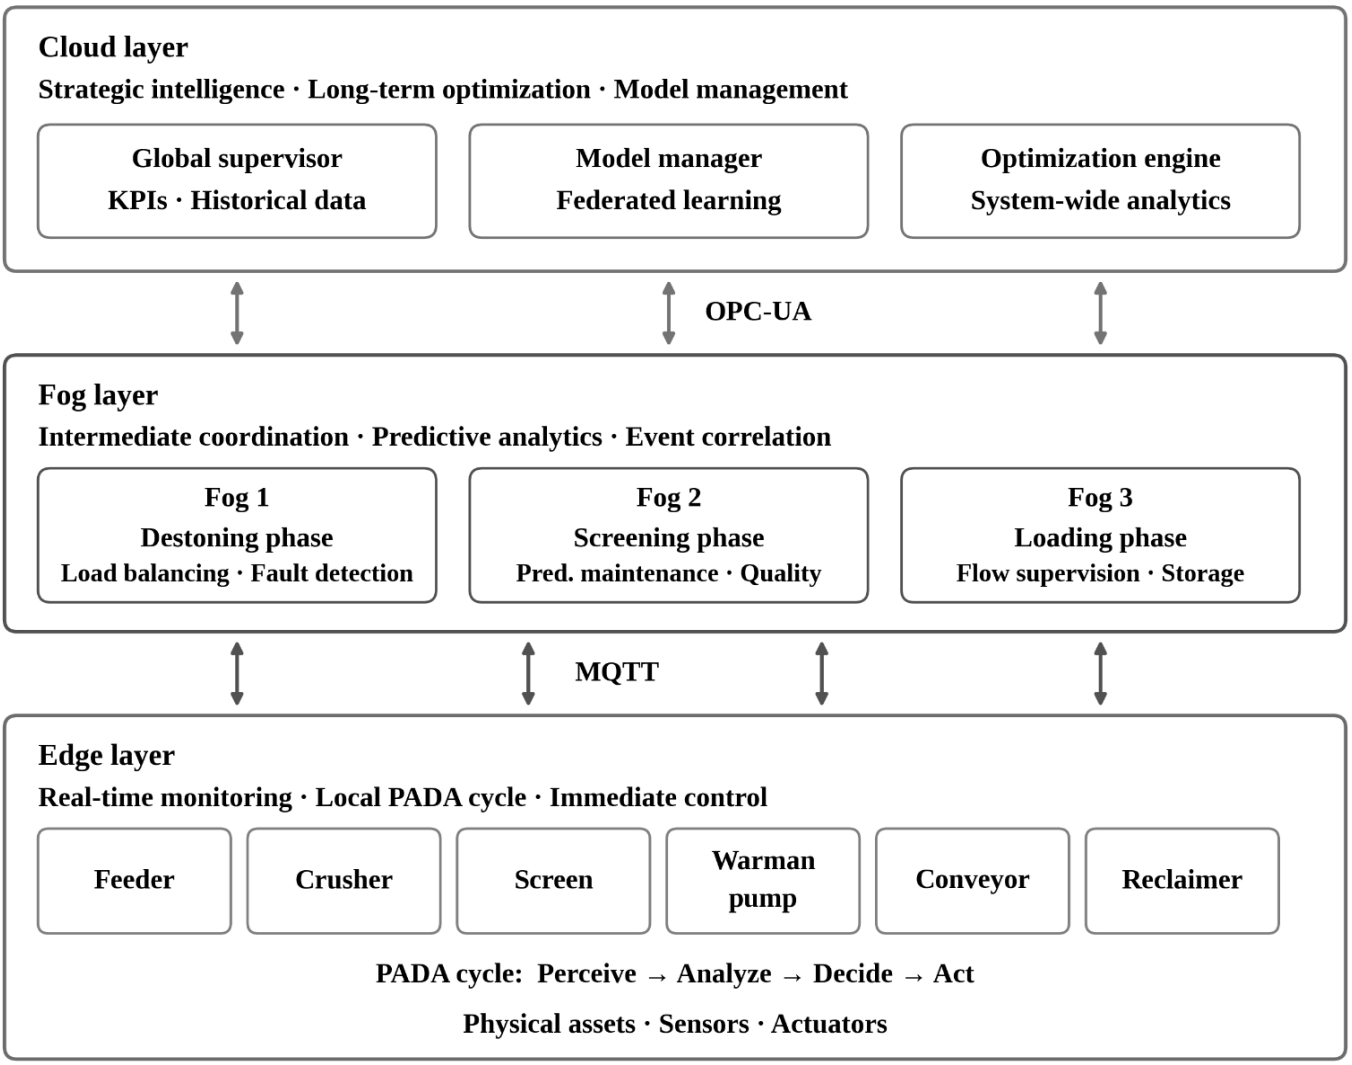

Fig. 1. Distributed edge-fog-cloud architecture.

C. Formal Modeling of Intelligent Entities

One of the limitations frequently observed in existing Industry 4.0 architectures concerns the lack of formal models capable of explicitly describing intelligent industrial entities and their role within distributed environments. Although concepts such as Cyber-Physical Systems, Industrial Internet of Things, and Multi-Agent Systems are widely adopted in the literature, the internal structure of intelligent components is often described at a conceptual level, making implementation, comparison, and reproducibility more difficult [5], [6]. This issue becomes particularly important in distributed architectures where multiple autonomous entities interact continuously across different decision layers.

To address this limitation, the proposed architecture introduces a formal model of intelligent entities that serves as the fundamental building block of the distributed intelligent system. The objective of this model is to provide a unified representation applicable to all components of the architecture, regardless of whether they operate at the Edge, Fog, or Cloud level. Such a representation facilitates system design, interoperability, scalability, and future extensions while maintaining a consistent architectural framework.

In the context of this work, an intelligent entity is defined as an autonomous component capable of perceiving its environment, processing information, making decisions, executing actions, and interacting with other entities through standardized communication mechanisms. This definition encompasses both physical and software components. For example, an Edge node attached to a feeder, a predictive maintenance service deployed at the Fog layer, and a federated learning module operating in the Cloud can all be represented using the same formal model.

Formally, each intelligent entity is represented by the following seven-component tuple:

$$E = (Id, P, S, D, A, C, I) \quad (1)$$

where, (Id) denotes the identity of the entity, (P) represents perception mechanisms, (S) defines the internal state, (D) corresponds to decision-making functions, (A) represents executable actions, (C) denotes communication capabilities, and

(I) describes integration constraints. As illustrated in Fig. 2, the proposed model organizes the behavior of each intelligent entity around seven complementary dimensions that collectively capture its operational, cognitive, and interactional characteristics. The model provides a common abstraction layer that can be applied consistently across the entire architecture.

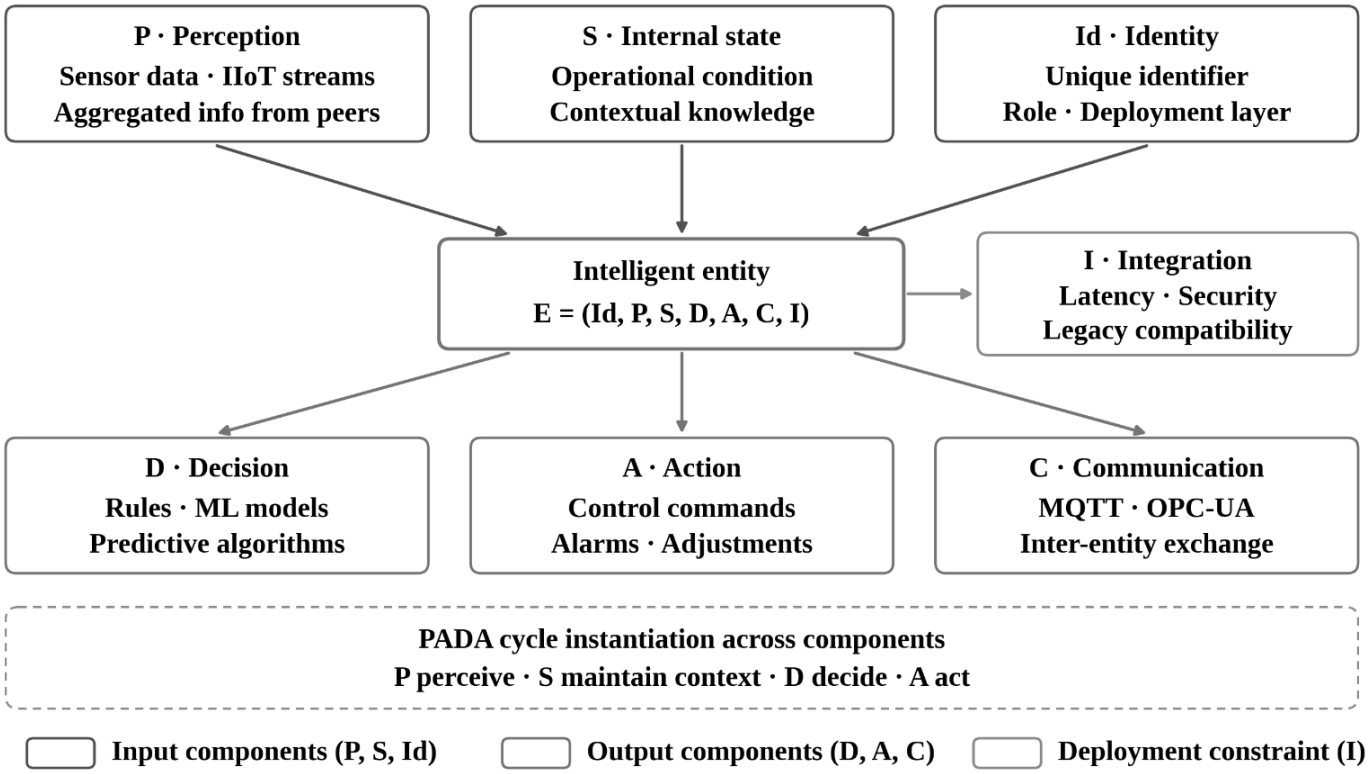

Fig. 2. Formal intelligent entity model.

The identity component ((Id)) uniquely identifies each entity within the architecture. Beyond simple identification, this component enables traceability, resource management, and coordination among distributed entities. It also facilitates the organization of entities according to their functional role and deployment layer.

The perception component ((P)) represents the mechanisms through which an entity acquires information from its environment. Depending on the architectural level, perception may involve direct acquisition of physical measurements from sensors, reception of processed data from neighboring entities, or access to aggregated information originating from higher layers. Perception constitutes the entry point of the intelligent decision cycle and provides the information required for subsequent analysis [19], [20].

The state component ((S)) captures the current operational condition of the entity. It includes both instantaneous observations and contextual information derived from previous interactions. Maintaining an internal state allows entities to preserve operational context and supports adaptive behavior in dynamic industrial environments.

The decision component ((D)) contains the mechanisms responsible for transforming information into decisions. These mechanisms may rely on predefined rules, machine learning models, predictive algorithms, or hybrid approaches depending on the complexity of the task and the computational resources available at each architectural layer. The explicit representation of decision capabilities is particularly important in distributed intelligent systems because it clarifies where and how decisions are generated [10].

The action component ((A)) defines the set of operations that an entity can perform once a decision has been produced. Actions may include local control commands, alarm generation, parameter adjustments, maintenance recommendations, or communication with other entities. Through this component, decisions are translated into observable effects on the industrial environment.

The communication component ((C)) represents the interfaces and protocols that enable information exchange among distributed entities. Communication plays a central role in maintaining coordination across Edge, Fog, and Cloud layers. It allows entities to share operational information, synchronize their activities, and contribute to collective decision-making processes [3], [4].

Finally, the integration component ((I)) captures the constraints that govern the deployment and operation of the entity within an industrial environment. These constraints may include latency requirements, computational limitations, security policies, interoperability standards, and compatibility with legacy industrial systems. By explicitly incorporating integration aspects into the model, the architecture addresses one of the major challenges of Industry 4.0 adoption, namely the

coexistence of modern intelligent services with existing industrial infrastructures [5], [19].

More precisely, Id is drawn from the set of unique entity identifiers; P maps observable inputs to perceived information; S belongs to the entity state space and contains current and retained context; D maps perceived information and state to an admissible decision; A maps a selected decision to an executable action; C defines the permitted messages, interfaces, and communication protocols; and I contains integration constraints, including latency, resource, interoperability, security, and safety requirements.

At the architectural level, entity behavior is represented as a transition system whose principal states correspond to Perceive, Analyze, Decide, Act, Degraded, and Recovery. A valid perception updates the entity state and enables analysis; an analysis result enables a decision when its confidence and validity conditions are satisfied; an authorized decision enables an admissible action; and completion or rejection of the action returns the entity to perception. Communication loss or node failure triggers a transition to Degraded, whereas restored connectivity triggers Recovery and controlled resynchronization before normal operation resumes.

The representation is governed by four architectural invariants: each entity has a unique identity; every executed action is traceable to an originating state and decision; an action must satisfy the constraints contained in I before execution; and loss of higher-level connectivity must not disable the locally designated critical functions. These invariants define requirements for a future executable specification. They are not presented here as mechanically verified properties.

The proposed model provides a consistent structural representation for intelligent entities participating in the architecture. By bringing perception, state management, decision-making, action execution, communication, and integration constraints into a single framework, it establishes a basis for distributed coordination across operational levels. The tuple does not constitute a complete formal verification framework: detailed data types, protocol semantics, executable transition guards, temporal properties, and proof obligations remain to be specified in implementation-oriented formalism.

D. Distributed Cognition Model

The effectiveness of a distributed intelligent architecture depends not only on the way computational resources are organized but also on how cognitive functions are distributed throughout the system. While many Industry 4.0 architectures incorporate advanced analytics, machine learning algorithms, or autonomous agents, the cognitive processes underlying decision-making often remain implicit. As a result, it becomes difficult to understand how information is transformed into actions and how decisions generated at different architectural levels remain coherent [5], [6], [21].

To address this challenge, the proposed architecture adopts a distributed cognition model based on the PADA cycle, which consists of four successive phases: Perceive, Analyze, Decide, and Act. The model provides a unified decision-making framework that can be instantiated across all intelligent entities regardless of their role or deployment layer. Rather than concentrating cognitive functions within a centralized controller, cognition is distributed among Edge, Fog, and Cloud entities according to their operational responsibilities and decision horizons.

The PADA model is directly connected to the formal intelligent entity model introduced in Section II-C. The perception component ((P)) supports information acquisition, the state component ((S)) maintains contextual knowledge, the decision component ((D)) generates decisions, and the action component ((A)) executes the selected responses. Through this integration, intelligent entities become autonomous cognitive units capable of interacting with their environment while remaining coordinated within the overall architecture.

The first phase of the cycle, Perceive, is responsible for acquiring information from the environment. Depending on the architectural level, perception may involve physical measurements collected from sensors, aggregated operational information received from neighboring entities, or global performance indicators obtained from higher-level services. The quality and relevance of the perceived information directly influence the effectiveness of subsequent cognitive processes.

The second phase, Analyze, transforms raw observations into meaningful knowledge. This phase may involve data filtering, event correlation, anomaly detection, predictive analytics, or machine learning inference. The objective is not merely to process information but to contextualize it and extract actionable insights. Several studies have emphasized the importance of contextual analysis in distributed industrial systems, particularly when multiple heterogeneous data sources must be combined to support decision-making [10], [12].

The third phase, Decide, generates an appropriate response according to the current state of the entity and the operational objectives of the system. Decisions may be derived from expert rules, optimization criteria, predictive models, or hybrid approaches. Because decision-making responsibilities are distributed across multiple architectural levels, decisions are generated locally whenever possible and escalated only when a broader operational context is required.

The final phase, Act, translates decisions into operational actions. Depending on the layer involved, actions may correspond to equipment control commands, alarm generation, maintenance recommendations, policy dissemination, or model updates. Through this phase, cognitive processes produce measurable effects on the industrial environment and contribute directly to system performance.

Fig. 3 illustrates how the PADA cycle is instantiated across the three architectural layers of the proposed framework.

PADA is conceptually related to established feedback and cognitive cycles. MAPE-K separates monitoring, analysis, planning, and execution around an explicit knowledge base [21]; OODA emphasizes rapid observation, orientation, decision, and action; and Sense-Plan-Act links perception to planning and control. PADA does not claim to replace these models or to introduce an entirely new feedback-loop principle. Its contribution in this work is architectural: the same Perceive-Analyze-Decide-Act structure is instantiated at Edge, Fog, and Cloud levels and coupled with decision subsidiarity, escalation,

and graceful degradation. Compared with MAPE-K, contextual knowledge is represented within the entity state S rather than as a separate shared component, while the Decide phase may include rule selection, planning, or optimization according to the layer concerned.

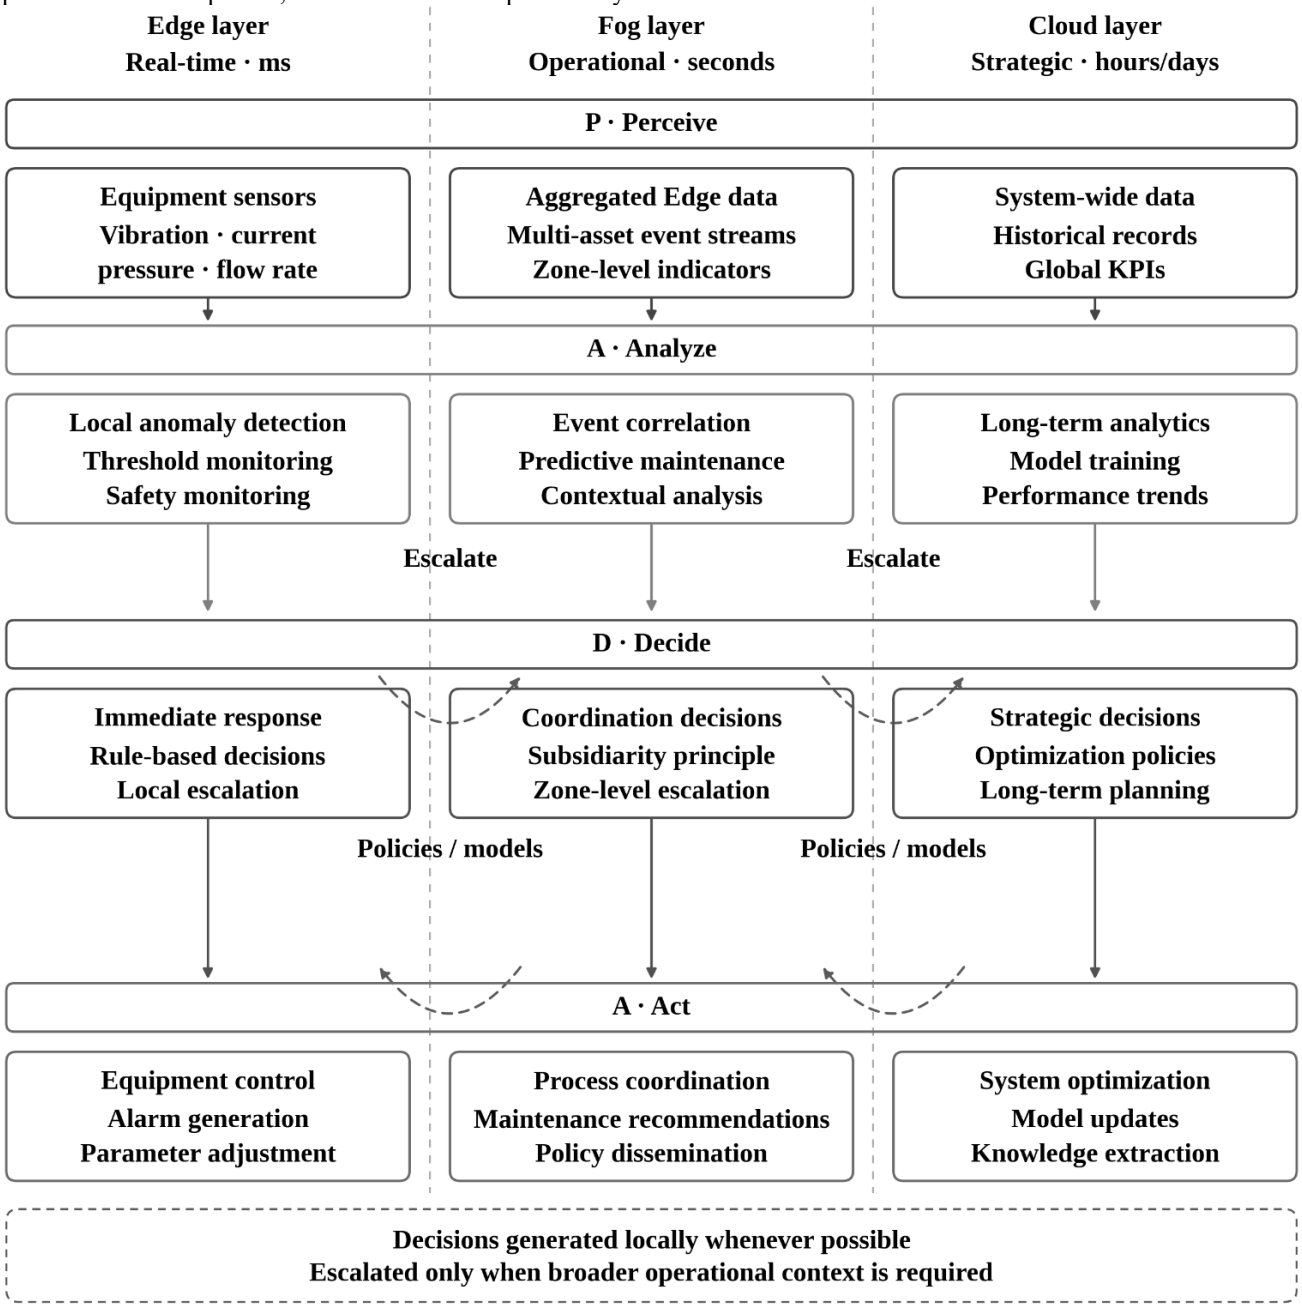

Fig. 3. PADA cycle distribution across the three-layer architecture.

The transition from one PADA phase to the next is conditional rather than purely sequential. Perception proceeds to analysis only when input validity requirements are met; analysis proceeds to decision when sufficient context or confidence is available; decision proceeds to action only when authorization, safety, and integration constraints are satisfied. Otherwise, the entity may retain the event, request additional context, escalate it to a higher layer, or enter a safe degraded state. These rules provide interaction semantics at the architectural level, while application-specific guards and thresholds remain implementation parameters.

A distinctive characteristic of the proposed approach is the distribution of cognition across multiple temporal horizons. At the Edge layer, the PADA cycle operates under strict real-time constraints and focuses on immediate operational events. Typical examples include anomaly detection, local safety monitoring, and equipment supervision.

At the Fog layer, cognition supports contextual analysis, predictive maintenance, event correlation, and operational coordination. Finally, at the Cloud layer, cognitive processes are oriented toward strategic optimization, knowledge extraction, model management, and long-term planning.

This hierarchical organization enables the architecture to combine local responsiveness with global consistency. Immediate decisions can be taken close to the physical process while strategic decisions benefit from a broader operational perspective. Consequently, the proposed architecture avoids the limitations of purely centralized systems while preserving coordination among distributed intelligent entities.

By introducing a common cognitive framework across all decision levels, the PADA model provides a coherent foundation for distributed intelligence, facilitating scalability, adaptability, and resilience in complex Industry 4.0 environments.

E. Coordination and Communication Mechanisms

The effectiveness of a distributed intelligent architecture depends not only on the capabilities of individual entities but also on their ability to exchange information and coordinate decisions. In Industry 4.0 environments, where cyber-physical systems, intelligent services, and connected devices operate simultaneously, maintaining consistency between local autonomy and global objectives becomes a major challenge [5], [6], [10].

To address this requirement, the proposed architecture adopts a hierarchical communication framework spanning the Edge, Fog, and Cloud layers. Rather than relying on centralized control, coordination is achieved through structured information exchanges and distributed decision-making processes.

Communication between Edge entities and Fog nodes is implemented through the MQTT protocol. Its lightweight publish–subscribe model makes it particularly suitable for Industrial Internet of Things environments characterized by resource-constrained devices and continuous data exchanges [10]. Edge entities publish operational data, alarms, and equipment states, while Fog nodes subscribe to the information relevant to their production area. This mechanism improves scalability and reduces communication overhead.

The Fog layer acts as the primary coordination level of the architecture. By aggregating information originating from multiple Edge entities, Fog nodes perform event correlation, predictive analytics, and operational supervision. This intermediate layer provides a broader operational context while preserving the responsiveness required for industrial processes [12], [13].

Communication between Fog and Cloud layers relies on OPC Unified Architecture (OPC-UA), a widely adopted standard for industrial interoperability and information exchange [22], [23]. Through OPC-UA, supervisory information, analytical models, and optimization policies can be exchanged in a structured and secure manner.

Coordination is further reinforced through decision subsidiarity. Local events are handled by Edge entities when the required information and authority are available, whereas decisions requiring a broader context or additional resources are escalated to Fog or Cloud levels [7], [24]. Each decision message is expected to carry its origin, scope, priority, timestamp, validity interval, and confidence. Safety-critical local actions take precedence over optimization requests; conflicting non-critical decisions are suspended and escalated to the responsible Fog node; and unresolved cross-zone conflicts are escalated to the Cloud supervisory level. These rules define a deterministic coordination policy rather than a distributed consensus protocol. To provide an implementation-oriented specification of this policy, Algorithm 1 describes local decision execution, priority-based conflict resolution, escalation, temporary Fog-level function takeover, and state reconciliation after connectivity restoration. The design of a distributed consensus protocol among equivalent Fog nodes remains outside the scope of this study.

Algorithm 1 specifies how each Edge entity processes observations and determines whether a decision can be executed locally or must be escalated. Local execution is permitted only when the decision satisfies the entity's authorization and safety constraints. When communication is unavailable, the entity activates its authorized degraded mode and buffers decisions and state updates. The procedure also defines deterministic priority rules for conflict resolution, temporary Fog-level takeover following an Edge-node failure, and state reconciliation after connectivity restoration. Although this specification improves the reproducibility of the coordination mechanism, its correctness and runtime performance remain to be evaluated through implementation and controlled experiments.

Algorithm 1: Distributed PADA Decision, Escalation, and Recovery Procedure

Initialize entity states S, decision rules R, authorization policies AP, priority levels PL, communication status CS, local state version V_E, and Fog state version V_F

Compute the initial connectivity and operational status of each Edge and Fog entity.

While the industrial system is operational, do

  For every Edge entity E_i do

    Acquire and validate observation o_i.

    Update internal state S_i using the validated observation.

    Execute the Perceive and Analyze phases of PADA.

    Compute candidate decision d_i using R and S_i

    Assign a priority according to safety, urgency, deadline, and operational impact.

    If d_i is locally authorized and satisfies the safety constraints, then

      Execute d_i at the Edge level.

      Record the action, timestamp, priority, and state version.

    Else if the Edge-Fog connection is available, then

Escalate d_i and its metadata to the associated Fog node.

If the Fog node detects conflicting decisions, then

Select the safety-critical decision.

Otherwise, select the decision with the highest priority.

When priorities are equal, select the earliest valid decision.

Escalate unresolved cross-zone conflicts to the Cloud

End if

Else

Activate the authorized degraded operating mode.

Buffer decisions and state updates with timestamps and sequence numbers.

End if

If E_i becomes unavailable, then

Reassign its critical monitoring functions to the associated Fog node.

Suspend functions that cannot be executed safely by the Fog node.

End if

If communication is restored, then

Transmit buffered records in sequence-number order.

Remove duplicate or invalid records.

Compare V_E with V_F

If a state conflict is detected, then

Preserve previously executed safety-critical actions.

Apply the most recent authorized consistent state.

Record the reconciliation result in the audit log.

End if

Resume normal PADA operation.

End if

End for

End while

A production implementation must complement this coordination policy with mutual authentication, role- or attribute-based authorization, encryption in transit, key management, audit logging, trust assessment, compromised-node detection, privacy controls, and safety interlocks. Fog-based security mechanisms can support distributed threat detection in large-scale IIoT environments [25]. These controls are architectural requirements associated with the integration component I; their implementation and security evaluation are outside the scope of the present study.

F. Resilience and Graceful Degradation

Resilience is a fundamental requirement for distributed industrial architectures, where communication failures, node outages, and infrastructure disruptions can compromise operational continuity [26]. Rather than assuming permanent availability of all system components, the proposed architecture adopts a graceful degradation strategy that preserves essential functions under partial failures. This approach is grounded in the distributed nature of the PADA cycle: since intelligent entities operate autonomously, they retain local perception, analysis, decision, and action capabilities even when connectivity with higher layers is interrupted [8], [26], [27].

Three degradation levels are considered. At the first level, Edge entities lose connectivity with their Fog node. In this case, they switch to autonomous mode, buffer operational data locally, and maintain critical functions such as anomaly

detection and safety monitoring until communication is restored. At the second level, Fog–Cloud connectivity is lost. Fog nodes continue operating using locally available information and previously received models, preserving event correlation, predictive maintenance, and coordination functions. Strategic optimization is temporarily suspended, but operational continuity is maintained [6], [8]. At the third level, a Fog node fails entirely. Neighboring Fog nodes dynamically assume coordination responsibilities for the affected zone, preventing isolated production areas [8], [26].

Once normal conditions are restored, the architecture initiates a progressive resynchronization process, redistributing buffered data, updated models, and optimization policies across all layers. Fig. 4 illustrates these three degradation levels and their corresponding recovery mechanisms.

The considered failure model covers communication-link loss and crash-stop unavailability of an Edge, Fog, or Cloud component; Byzantine behavior and compromised nodes are not modeled. Failures would be detected through configurable heartbeat timeouts, missed-message counts, and local health checks, with threshold values determined during implementation. Buffered records should carry timestamps, sequence numbers, and model or policy versions. Recovery should use idempotent replay, duplicate suppression, and version checks; when concurrent updates conflict, the responsible Fog node should retain safety-critical local actions and reconcile non-critical state according to the most recent valid policy. These mechanisms are specified as design requirements and have not yet been experimentally evaluated for consistency, recovery time, or availability.

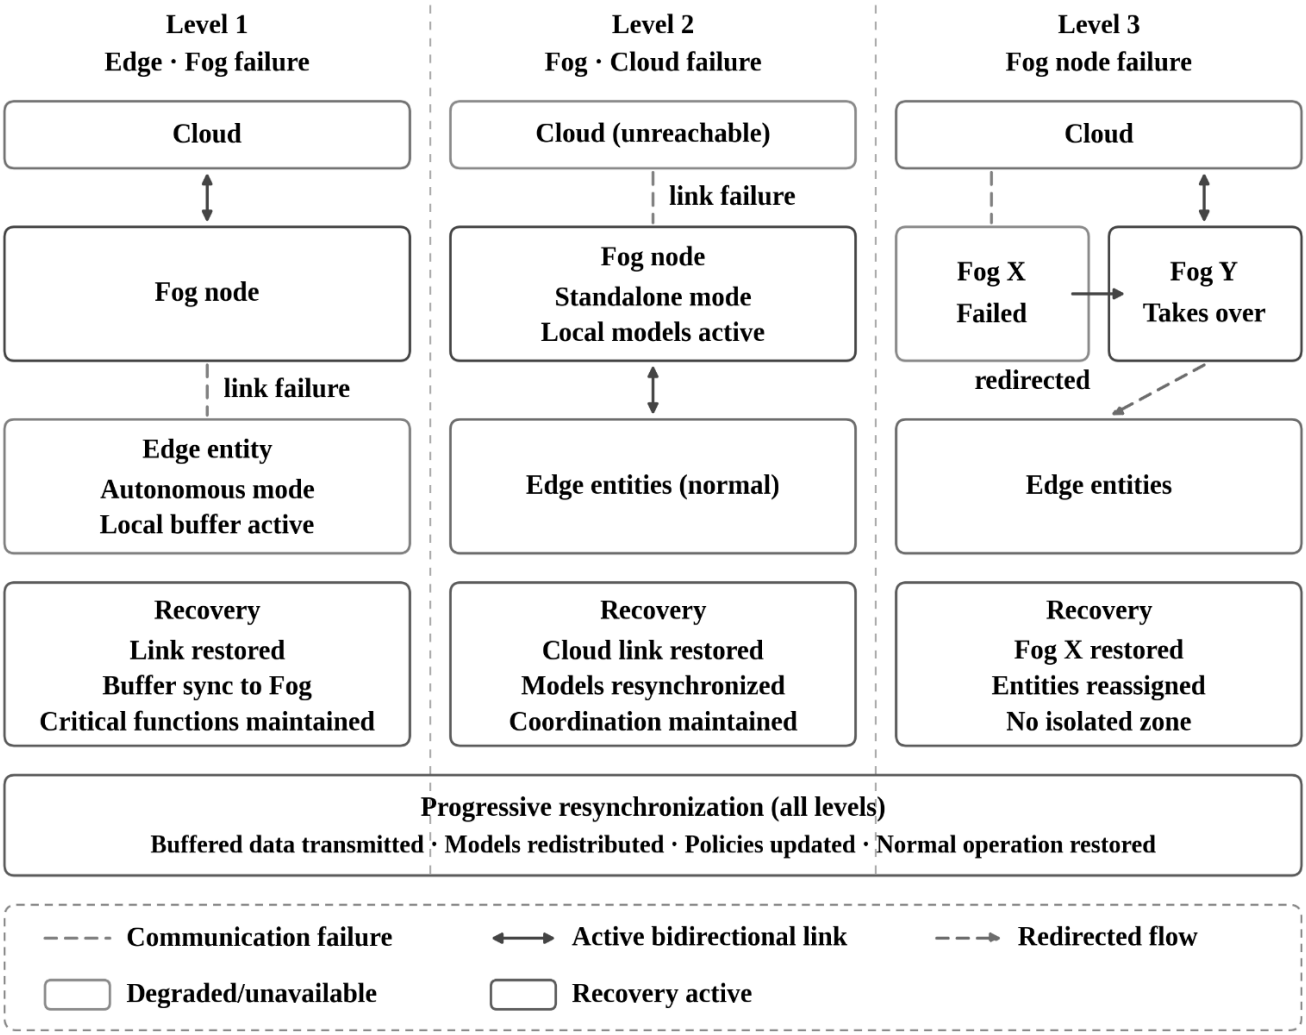

Fig. 4. Three-level graceful degradation and recovery mechanisms.

III. Industrial Case Study and Proposed Deployment Scenario

The fixed phosphate-processing facilities of the OCP Benguerir mining site are adopted as an industrial case study for defining the proposed deployment scenario. The architecture has not been physically deployed at the site, and this study does not use operational logs, field measurements, or observed system behavior as validation evidence. The production line is represented through three interconnected phases: destoning, screening, and loading. Their equipment, data sources, decision horizons, and continuity requirements provide an industrially grounded context for the architectural mapping [2], [5], [23], [28].

In the proposed mapping, Fog 1 would supervise feeders, crushers, and conveyors in the destoning phase, focusing on load balancing and fault detection. Fog 2 would coordinate screens, hydrocyclones, and Warman pumps in the screening phase, supporting predictive maintenance and quality monitoring [29]. Fog 3 would manage material-flow supervision and storage coordination during loading. This three-node organization follows the operational boundaries represented in the case study and is not a record of installed Fog infrastructure [8], [30].

In this scenario, intelligent Edge entities would be associated with the main assets of each phase and would execute local PADA cycles for monitoring, anomaly detection, and authorized immediate control. At the Cloud level, historical data and performance indicators would be consolidated for global supervision and long-term optimization. Table I summarizes this proposed mapping between production phases, equipment, and architectural components [5], [8], [31].

An illustrative data flow begins when a vibration sensor associated with a Warman pump produces a new observation. The Edge entity perceives and validates the measurement, updates its internal state, analyzes it against the configured anomaly rule or model, and either records a normal condition or issues an authorized local alarm. Events requiring wider context are published to Fog 2, which correlates them with other screening assets and may generate a maintenance recommendation. Relevant summaries can subsequently be transmitted to the Cloud for historical analysis and model management. This example explains the intended information flow; it is not an operational trace collected from the OCP site.

TABLE I. PROPOSED DEPLOYMENT OF INTELLIGENT ENTITIES FOR THE OCP BENGUERIR CASE STUDY

Production Phase	Main Equipment	Intelligent Edge Entities	Fog Node	Primary Functions
Destoning	Feeders, Crushers, Conveyors	Equipment-level entities	Fog 1	Monitoring, anomaly detection, local control
Screening	Screens, Hydrocyclones, Warman Pumps	Equipment-level entities	Fog 2	Predictive maintenance, coordination, quality monitoring
Loading	Conveyors, Reclaimers, Storage Silos	Equipment-level entities	Fog 3	Material flow supervision, operational coordination

IV. COMPARATIVE ANALYSIS

To position the proposed architecture within the current state of the art, this section compares it with three representative families of Industry 4.0 architectures identified in the literature, namely Cyber-Physical System (CPS)-based architectures, Multi-Agent System (MAS)-based architectures, and conventional Edge-Fog-Cloud architectures. The comparison is based on six descriptive dimensions: multi-level intelligence, entity representation, explicit cognition cycle, decision subsidiarity, graceful degradation, and illustration or validation basis. The comparison results are summarized in Table II.

CPS-based architectures [5], [23], [24] provide robust integration between physical assets and computational services, with a strong emphasis on connectivity, interoperability, and data management. However, they do not explicitly define a formal model for intelligent entities, nor do they distribute cognition across multiple architectural levels. MAS-based approaches [10], [11] naturally support distributed decision-making through autonomous agents but lack a unified representation applicable to heterogeneous industrial components deployed across Edge, Fog, and Cloud layers. Furthermore, large-scale coordination and integration with IIoT infrastructures remain challenging. Conventional Edge-Fog-Cloud architectures [3], [4], [13], [32] efficiently distribute computation to improve latency and scalability, but intelligence, decision-making, and resilience are generally implemented at the application level rather than being embedded into the architecture itself.

The proposed architecture combines a structural entity representation, a distributed PADA cycle, decision subsidiarity, and a conceptually specified degradation strategy. Table II indicates whether these capabilities are explicit, partial, or implementation-dependent within each architectural family. This qualitative comparison does not establish architectural completeness or performance superiority. Individual implementations may provide capabilities that are not captured by the selected dimensions.

TABLE II. COMPARISON OF REPRESENTATIVE INDUSTRY 4.0 ARCHITECTURES

Feature	CPS	MAS	Conventional EFC	Proposed framework
Multi-level intelligence	Partial	Supported	Partial	Explicit
Entity representation	Varies	Agent-based	Usually implicit	Seven-component model
Explicit cognition cycle	Usually implicit	Partial	No	PADA
Decision subsidiarity	Partial	Supported	Partial	Explicit
Graceful degradation	Implementation-specific	Implementation-specific	Partial	Conceptual
Illustration or validation basis	Varies	Varies	Varies	OCP conceptual case

V. DISCUSSION

The proposed architecture integrates intelligent entity representation, distributed cognition, hierarchical coordination, and graceful degradation within a unified Edge, Fog, and Cloud framework. The seven-component model clarifies the responsibilities of each entity, while PADA connects perception and internal state to decisions and actions. However, this architectural integration does not demonstrate better latency, availability, or scalability. These properties depend on the implementation, workload, network conditions, and available resources.

Distributing PADA across the three levels presents several trade-offs. Edge entities can process data close to industrial equipment and maintain selected functions during communication failures. This improves local autonomy but increases processing, storage, update, and safety requirements. At the Fog level, data aggregation provides a broader operational context. However, coordination and state synchronization may increase communication overhead as the number of entities grows. Recent studies confirm that task allocation and resource management influence the performance of collaborative Edge, Fog, and Cloud architectures [14], [15], [18].

The combined use of MQTT and OPC UA also introduces integration constraints. It may require protocol adaptation, shared information models, quality of service configuration, and duplicate message management. A physical implementation reported in [16] confirms the feasibility of combining local acquisition, preprocessing, and cloud transmission. Nevertheless, its experimental context differs from the industrial scenario considered in this work.

Decision subsidiarity creates a balance between local responsiveness and global consistency. An Edge entity may act before receiving a higher-level decision. Subsequent synchronization may then reveal conflicting states or policies. The proposed priorities, escalation rules, buffering, versioning, and resynchronization mechanisms provide an architectural basis for managing this issue.

Algorithm 1 specifies deterministic rules for conflict resolution, escalation, temporary Fog-level function takeover, and post-reconnection synchronization. Their implementation as executable software and the development of a distributed consensus protocol among equivalent Fog nodes remain future work.

Graceful degradation allows selected functions to continue during communication or node failures. This principle is consistent with existing work on fault-tolerant degradation and resilient distributed architectures [17], [27]. Its effectiveness must nevertheless be evaluated through failure injection and metrics such as availability, recovery time, message loss, and data consistency.

Security is also essential in distributed IIoT environments. Authentication, authorization, encryption, trust management, audit logging, and compromised node detection should be included in future implementation. Fog-based mechanisms can support distributed threat detection [25], but they also introduce processing and communication overhead.

The comparison in Table II is qualitative and does not demonstrate the superiority of the proposed architecture. Similarly, the OCP Benguerir case study represents a conceptual mapping rather than a physical deployment. No operational data, logs, or field measurements from OCP are used as validation evidence.

A. Limitations and Future Validation

This study is limited to architectural design, structural formalization, and qualitative analysis. Although the seven-component tuple defines the principal responsibilities of an intelligent entity, it does not yet constitute a complete executable or mechanically verified formal model. Detailed data types, temporal constraints, transition guards, proof obligations, and protocol semantics remain to be defined using an implementation-oriented formalism.

Algorithm 1 provides an implementation-oriented pseudocode specification of the PADA coordination and recovery mechanisms. However, it has not yet been implemented as executable software or evaluated under runtime conditions. The OCP Benguerir case represents a proposed architectural mapping without operational data, logs, or field measurements. Authentication, authorization, encryption, trust management, compromised-node detection, privacy protection, and industrial safety controls are identified as requirements but have not been implemented or evaluated. Consequently, the present results should not be interpreted as evidence of operational performance, availability, resilience, or scalability.

Validation should proceed in successive stages. The first stage should provide an executable specification of the entity transitions and architectural invariants. The second stage should implement a small-scale prototype or simulation of the distributed PADA cycle. The third stage should introduce controlled Edge-Fog, Fog-Cloud, and Fog-node failures. The evaluation should measure end-to-end latency, decision time, availability, recovery time, communication overhead, CPU and memory utilization, message loss, data consistency, and scalability under normal and injected-failure conditions.

A subsequent industrial pilot would then be required to compare experimental results with operational measurements and assess interoperability, safety, cybersecurity, and long-term reliability under field conditions.

VI. Conclusion

This study proposed a distributed intelligent Edge-Fog-Cloud architecture for Industry 4.0 systems. It integrates a structural seven-component entity representation, a distributed PADA cognition cycle, decision subsidiarity, and a three-level graceful degradation strategy. The contribution is architectural and qualitative. It organizes these mechanisms within a common representation across the Edge, Fog, and Cloud levels.

The seven-component tuple makes entity responsibilities and constraints explicit, while PADA links perceived information and internal states to decisions and actions at different temporal and operational horizons. The proposed transition rules, invariants, escalation metadata, and recovery requirements strengthen the specification. However, they do not constitute a complete executable or mechanically verified model.

The qualitative comparison positions the framework relative to broad CPS, MAS, and conventional Edge-Fog-Cloud architecture families without claiming universal superiority. Its main value lies in making entity representation, distributed cognition, decision subsidiarity, and graceful degradation explicit within a unified design. The associated resource requirements, coordination overhead, protocol integration, state reconciliation, and security costs remain to be quantified.

The OCP Benguerir case study illustrates a proposed mapping of intelligent entities to a realistic phosphate-processing context. It does not represent a physical deployment or provide operational evidence of performance. The applicability of the framework to other industrial domains must therefore be examined through implementation and comparative evaluation.

Future work will develop an executable prototype or simulation environment for the proposed architecture. The evaluation will implement conflict resolution, task reassignment, Fog-node takeover, post-reconnection synchronization, and security controls. It will measure latency, availability, recovery time, communication overhead, resource utilization, data consistency, and scalability under normal and injected-failure conditions. A subsequent industrial pilot will be required to assess interoperability, safety, and operational effectiveness under field conditions.

***Abstract*—Accurate robotic positioning is essential in automated marking because residual pose error directly shifts the permanent mark. This study presents a one-step vision-based residual error compensation method that measures the displacement between the target and the marking-tool position after the initial robot motion, transforms that displacement into the robot base frame, and applies it as a translational Tool Center Point (TCP) correction. The platform combines an AR4-MK3 six-degree-of-freedom manipulator, a fixed Intel RealSense D455 RGB-D camera, and a 50 W electromagnetic marking device. At five spatially distinct target points, the mean Euclidean positioning error decreased from 7.40 ± 1.35 mm to 2.14 ± 0.36 mm. The mean paired decrease was 5.26 mm (95% confidence interval: 4.04-6.48 mm), and all five points improved by 70.7%-71.4%. An exploratory point-level paired test gave $t(4) = 11.92$ and $p < 0.001$. The result supports the feasibility of inserting a local visual correction immediately before marking without changing the nominal robot kinematic model. The evaluation is a five-point pilot rather than a repeatability or full workspace study; raw repeated-trial, orientation-error, timing, robustness, and quantitative mark-quality measurements were not available. The conclusions are therefore limited to translational positioning under the tested camera and workcell configuration.**

I. Introduction

Industrial robots support welding, assembly, machining, inspection, material handling, and surface-processing operations because they combine programmable motion with high repeatability [1]. Repeatability, however, is not equivalent to absolute accuracy. Kinematic parameter errors, joint clearances, compliance, assembly tolerances, thermal effects, and environmental disturbances can displace the end-effector from a commanded Cartesian target [2]. These errors are important in marking because the final tool position determines the location of a permanent identifier.

Robot calibration and error compensation improve absolute positioning by identifying differences between nominal and actual robot behavior [3]. Kinematic calibration can reduce systematic geometric error, but non-kinematic effects such as compliance, thermal drift, payload, and base deformation may remain [4]. High-accuracy calibration also commonly uses laser trackers, coordinate-measuring machines, or photogrammetric systems, which improve traceability but increase workcell cost and integration effort [5].

Machine vision provides a complementary route because it observes the current relationship among the target, tool, and workpiece [6]. Vision-guided correction has been applied to machining, drilling, grinding, assembly, and navigation tasks [7]. In contrast to a purely global calibration model, a local measurement made after the initial robot motion can capture the net residual error produced by several upstream sources.

Prior work includes vision-guided robot localization [8], neural-network prediction of positioning error [9], and models that incorporate non-kinematic and weak rigid-base effects [10]. Hand-eye vision has also been used for indirect compensation [11], while photogrammetric calibration has improved camera-guided robot accuracy [12]. Recent studies additionally address uncertainty in TCP calibration [13], stereo-vision closed-loop measurement [14], and high-precision tool-path generation for engraving [15]. These approaches establish the value of external sensing, but many require global calibration, extensive data collection, iterative control, or specialized metrology.

Vision-based residual correction is well suited to automated marking. Even after the target is transformed into the robot coordinate system, the executed tool position can still contain errors from target localization, camera calibration, camera-to-robot registration, TCP definition, and manipulator mechanics. Because these errors accumulate along the measurement and positioning chain, the initially calculated TCP pose should not be treated as an error-free final command.

The proposed workflow inserts a single visual correction after the initial positioning motion and before tool activation. The camera measures the target-to-tool displacement; the displacement is expressed in the robot base frame, and the corresponding translational offset is added to the TCP command. The method does not replace robot or camera calibration; it compensates for the residual displacement that remains after those procedures.

The research gap is therefore application-specific rather than a claim that visual correction is new in itself. Existing studies mainly evaluate calibration, machining, drilling, assembly, or trajectory control. Automated marking requires target localization, frame transformation, residual error measurement, correction, and permanent mark execution to operate as one ordered sequence. A practical question is whether a simple pre-marking correction can improve a low-cost workcell without retraining a model or changing the nominal robot kinematics.

This study makes three contributions: 1) a marking-specific sense-correct-execute workflow that uses the same fixed RGB-D camera for initial localization and residual measurement; 2) an explicit frame-consistent formulation that transforms camera-space displacement before TCP correction; and 3) a transparent five-point pilot analysis that reports point-level dispersion, confidence intervals, and an exploratory paired comparison. The scope is translational correction under a fixed camera and fixed tool orientation. The study does not claim full six-degree-of-freedom compensation, industrial robustness, or metrological equivalence to a laser tracker.

II. Related Work

Industrial robot accuracy enhancement is commonly divided into kinematic calibration, extended error modeling, data-driven compensation, and external-sensor feedback. Kinematic methods identify geometric parameters from measured poses [16], whereas extended models incorporate compliance, backlash, base deformation, thermal effects, and load-dependent behavior [17]. Model-free methods learn commanded-to-measured error mappings [18], including neural, radial-basis, Gaussian-process, and other regression models [19]. Deep models can represent nonlinear workspace error [20], and similarity or incremental-learning strategies can reduce calibration effort [21]. These gains depend on the coverage and stability of the training data.

External metrology provides traceable end-effector measurements. Laser trackers are widely used for calibration and accuracy assessment [22], and real-time trajectory compensation can reduce path error [23]. Such systems offer higher accuracy than commodity RGB-D cameras but require line of sight, careful setup, and additional capital equipment. Visual guidance offers a lower-cost alternative for local correction. Examples include visually guided pose improvement in robotic machining [24], online visual correction for robotic drilling [25], and integrated machine-vision compensation architectures [26].

A reproducible visual correction chain requires both camera calibration and frame registration. Intrinsic calibration relates pixels and depth to camera-frame coordinates and is commonly estimated from multiple views of a calibration pattern [27]. Camera-to-robot registration is the hand-eye problem. Foundational solutions include the Tsai-Lenz method [28], separable rotation-translation estimation [29], Lie-group formulations of AX = XB [30], and dual-quaternion estimation [31]. Later work optimized pose selection [32], solved robot-world/hand-eye calibration jointly [33], and minimized reprojection error directly [34]. Reviews and comparative evaluations show that calibration accuracy depends on pose diversity, image localization error, and the selected solver [35]-[37].

The proposed correction is also related to image-based and position-based visual servoing. Classical visual servo control uses image or reconstructed pose error to generate motion commands [38]-[40], and modern robot-vision treatments emphasize explicit coordinate-frame conventions and stability assumptions [41], [42]. In multi-sensor systems, temporal and spatial calibration must be considered together when measurements and robot states are not synchronized [43]. Three-dimensional hand-eye calibration with line laser sensors [44] and learning-based vision for small and medium-sized production cells [45] further demonstrate the range of sensing and integration choices.

The Intel RealSense D455 is an active-stereo RGB-D device whose manufacturer specifies depth resolution up to 1280 x 720 and depth accuracy below 2% at 4 m under the stated test conditions [46]. Independent close-range characterization confirms that D455 performance varies with distance, surface geometry, and device-specific effects [47]. Evaluation under indoor mapping conditions also shows that measurement noise depends on range and surface inclination [48]. Consequently, a D455 cannot be treated as a substitute for a traceable metrology system, and its uncertainty forms part of the residual error reported in this study.

Published compensation results are not directly rankable because robots, workspaces, sensors, metrics, and test protocols differ. Accuracy and repeatability also change between offline and online robot-programming environments [49]. A laser-tracker and neural-network method reduced mean positioning error from 0.8497 to 0.0490 mm [50], while an offline deep-belief-network method reduced error from 0.469 to 0.084 mm [51]. Laser-tracker calibration has likewise demonstrated submillimeter improvement on industrial robots [52]. ISO 9283 provides standardized concepts for pose accuracy and repeatability [53], but the present pilot does not implement the complete standard protocol. Its contribution is the marking-specific local correction sequence, not superior absolute accuracy over these differently instrumented systems.

III. Materials and Methods

A. Experimental Vision-Guided Robotic Marking System

The experimental platform comprises an AR4-MK3 six-degree-of-freedom manipulator, a fixed Intel RealSense D455 RGB-D camera, a 50 W electromagnetic marking device, and a computer-based controller. The marking device is rigidly mounted on the robot end-effector. The camera observes the workpiece and tool from above in an eye-to-hand configuration. The camera was not moved during the reported five-point experiment.

The system uses two positioning stages. First, the target is localized from aligned color and depth data and transformed into the robot base frame to generate an initial TCP position. The robot then moves the marking tool to that command and comes to rest. Second, the vision system estimates the remaining target-to-tool displacement. After transforming the displacement into the base frame, the controller issues one corrected TCP command before activating the marking tool.

The controller performs image acquisition, target and tool localization, depth association, camera-to-base transformation, residual-error calculation, and robot command transmission. Fig. 1 identifies the interface view (left), the fixed camera and observed workpiece region (upper right), and the robot-mounted electromagnetic marking tool (lower right).

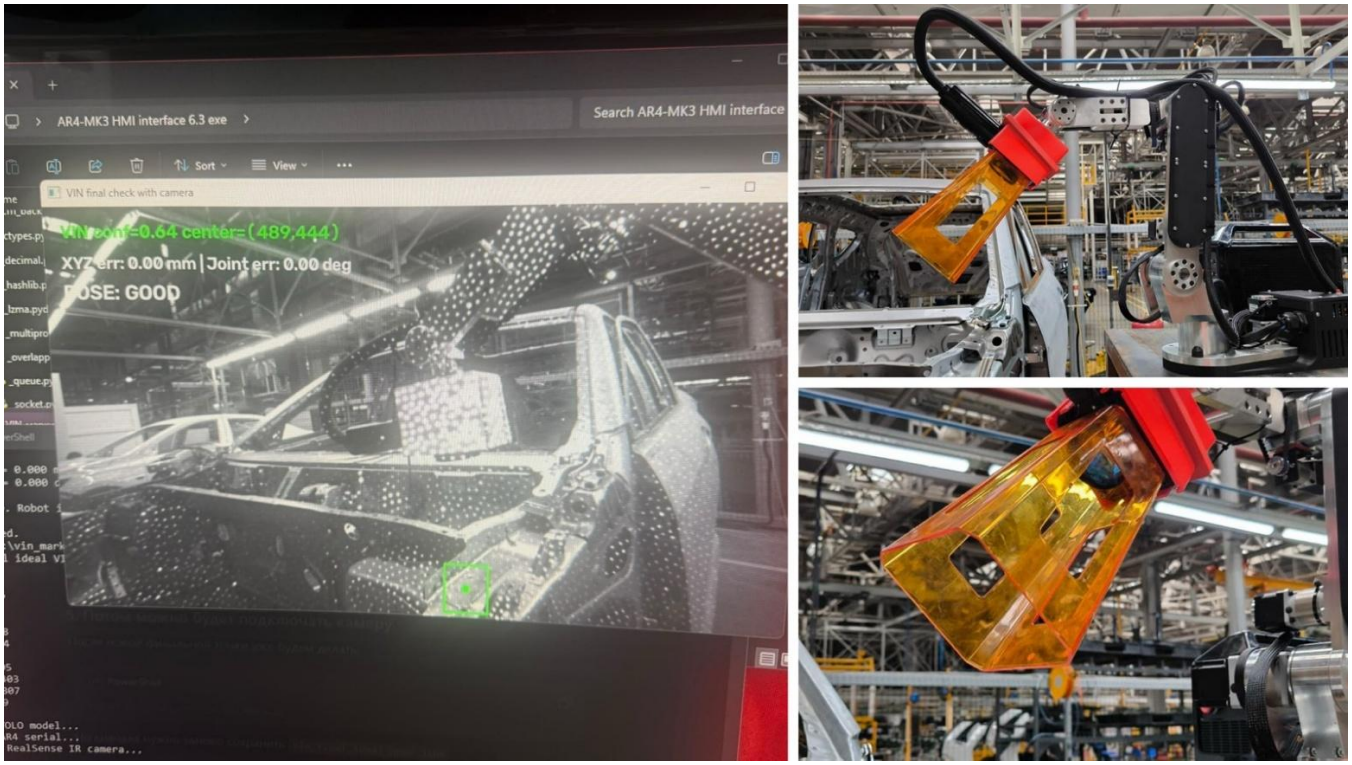

Fig. 1. Experimental vision-guided marking cell: camera and detection interface (left), fixed RGB-D camera and observed workpiece region (upper right), and AR4-MK3 manipulator with the electromagnetic marking tool (lower right).

B. Camera Calibration and Coordinate Frames

Four frames are used: the camera frame {C}, robot base frame {B}, TCP frame {T}, and workpiece/target frame {W}. The camera is fixed relative to the robot base. A camera-frame point p^c is mapped to the base frame by the homogeneous transformation $p^B = T\_BC\ p^c$, where T_BC contains the rotation R_BC and translation t_BC. The target and measured tool points are transformed independently before their difference is used for correction.

The intrinsic model deprojects an aligned pixel-depth observation according to $p^c = z\ K^{-1}\ [u, v, 1]^T$, where K is the camera intrinsic matrix and z is the depth associated with the detected image location. Target and tool image regions are localized by the workcell detector; the center of each detected region defines (u, v), and valid depth samples around that center are aggregated to suppress isolated depth outliers. This definition makes the visual measurement reproducible at the algorithmic level, although the detector version, exact acquisition resolution, calibration residuals, and per-frame raw observations were not retained in the experimental record.

The fixed eye-to-hand transformation T_BC was determined before the positioning experiment from paired camera-frame and robot-base observations and then held constant. The transformation must be validated in the actual work volume because intrinsic calibration error, target localization error, depth bias, and registration error propagate into the compensation vector. The original study did not archive an independent traceable uncertainty budget; consequently, the reported post-compensation error represents the combined robot-and-vision result rather than robot error alone.

C. Vision-Based Positioning Error Estimation

After the initial robot positioning, the camera observes the desired target and the marking-tool reference within the same scene. Let P_t and P_m denote their three-dimensional positions after deprojection and transformation into a common coordinate frame. The component-wise residual and Euclidean distance are defined in Eq. (1)-(7). In implementation, displacement E in {C} is rotated into {B} by R_BC; the translation t_BC cancels because E is a difference between two points.

Let the desired target position be defined as:

$$P_t = (x_t, y_t, z_t) \tag{1}$$

and the actual position of the marking tool after the initial robot movement as:

$$P_m = (x_m, y_m, z_m) \tag{2}$$

The positioning error along each coordinate axis is calculated as:

$$e_x = x_t - x_m \tag{3}$$

$$e_y = y_t - y_m \tag{4}$$

$$e_z = z_t - z_m \tag{5}$$

The resulting error vector is expressed as:

$$E = [e_x; e_y; e_z] \tag{6}$$

while the total positioning error is calculated using the Euclidean distance:

$$e = \mathrm{sqrt}\left(e_x^2 + e_y^2 + e_z^2\right) \quad (7)$$

The vector therefore represents both the magnitude and direction of the residual translation. Frame consistency is essential: a displacement measured in {C} cannot be added directly to a TCP position in {B}. Only the residual after rotation into {B} is passed to the compensation stage.

D. Proposed Error Compensation Method

The proposed method applies one translational correction after the initial motion. The initial TCP position is expressed in the robot base frame. The compensation offset is obtained from the camera-space residual through the rotation R_BC, and the corrected TCP position is transmitted as a second point-to-point command.

The initial TCP position is represented as:

$$P_{(TCP)} = \left[x_{(TCP)}; y_{(TCP)}; z_{(TCP)}\right] \quad (8)$$

Using the residual expressed in {C}, the base-frame compensation offset is defined as:

$$\Delta P^B = R_{BC} E^C \quad (9)$$

The corrected base-frame TCP position is then calculated as:

$$P_{TCP}^{corr} = P_{TCP} + \Delta P \quad (10)$$

or, in expanded base-frame form:

$$P_{TCP,corr}^B = [x_{TCP} + \Delta x^B, y_{TCP} + \Delta y^B, z_{TCP} + \Delta z^B]^T \quad (11)$$

The corrected position is transmitted to the robot controller only after the initial motion has settled. The tool orientation is held at the taught marking orientation and is not changed by the compensation algorithm. This design is appropriate for the planar workpiece used in the pilot, but it does not compensate for rotational error. Orientation error can change contact angle, normal force, and mark geometry and must be measured in a full six-degree-of-freedom extension.

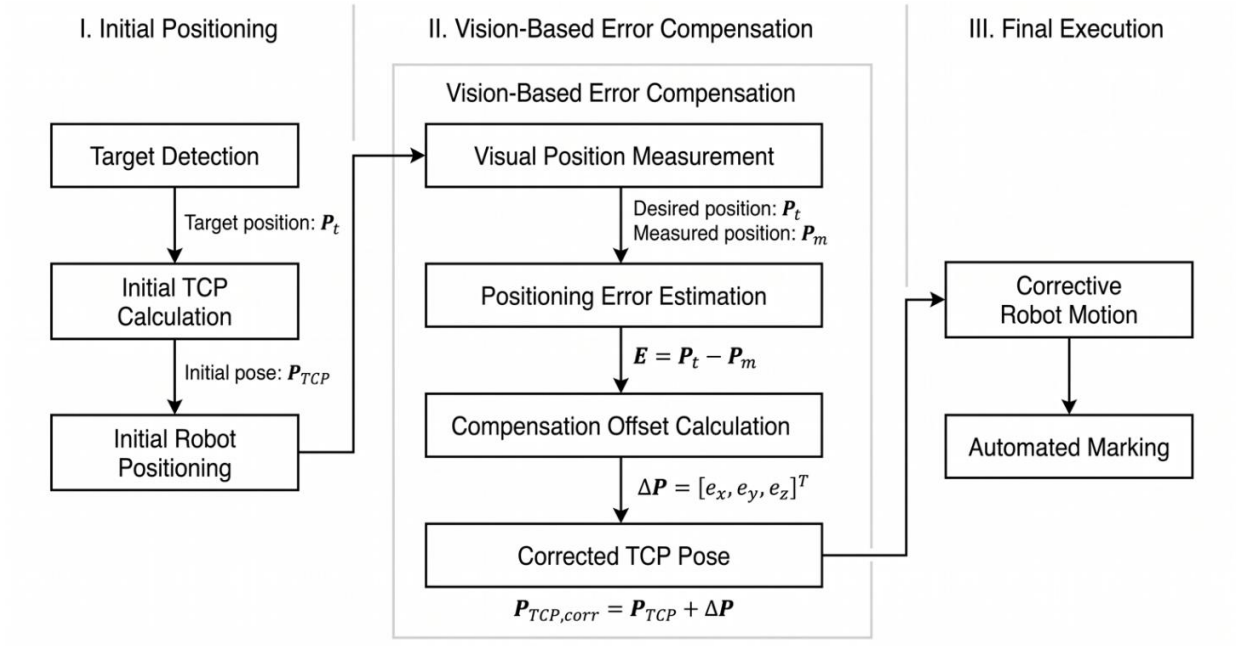

Fig. 2. Proposed vision-based error compensation framework for robotic positioning and automated marking.

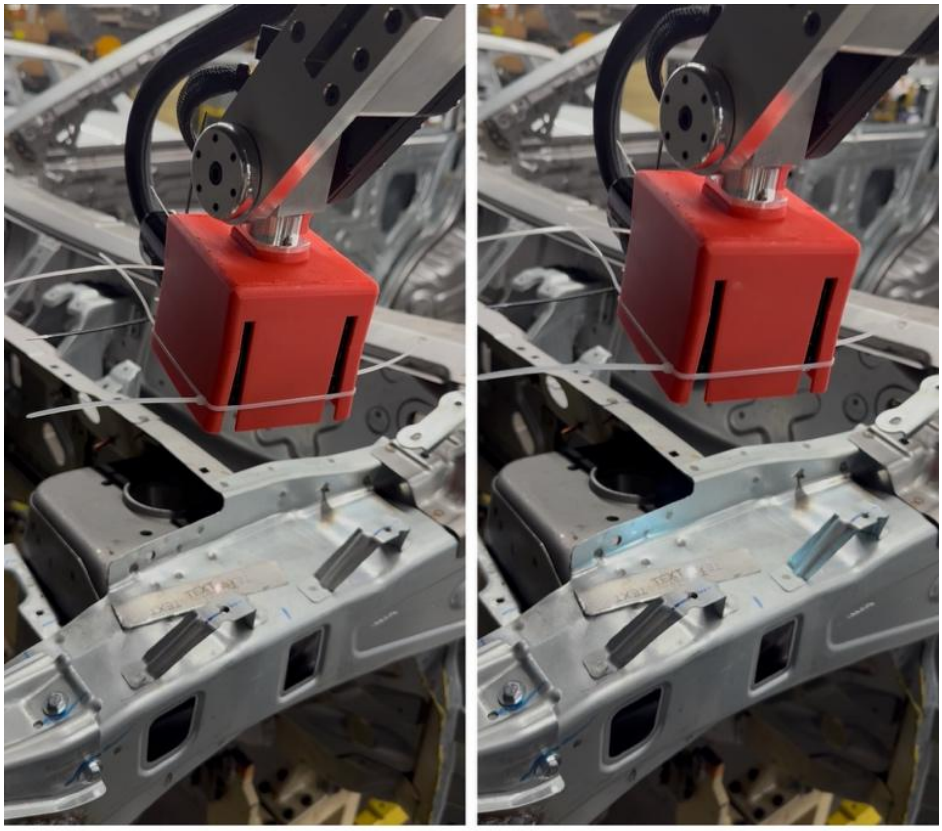
Fig. 2 summarizes the marking-specific sequence. In the schematic, ΔP denotes the frame-consistent offset defined formally in Eq. (9). The first command uses the transformed target position, and the second uses the residual displacement measured after the robot has settled. The technical distinction from global calibration and learned workspace compensation is that the proposed offset is local, task-timed, and calculated immediately before permanent marking. The approach still depends on valid camera calibration and does not remove the need for metrological validation.

E. Experimental Procedure

The method was evaluated at five distinct target locations, P1-P5, within the accessible marking area. At each location, the robot executed the initial target command, stopped, and was observed by the D455. The Euclidean tool-to-target distance was recorded before compensation. The base-frame correction was then applied, the robot stopped again, and the final distance was recorded. The retained dataset contains one before-and-after pair for each spatial target point. Although preliminary workcell operation involved repeated positioning, trial-level raw measurements and exact base-frame coordinates for P1-P5 were not preserved; the manuscript therefore treats the five sites, not repeated trials, as the experimental units and does not claim ISO 9283 repeatability.

The primary outcome was Euclidean positioning error in millimeters. Secondary descriptive outcomes were the absolute paired decrease and percentage reduction at each point. The uncompensated first command serves as the within-point open-

loop baseline. No independent calibrated-positioning baseline, orientation-error series, cycle-time log, or robustness series for illumination, camera displacement, vibration, and workpiece rotation was available. These omissions are stated explicitly so that the pilot is not interpreted as a full industrial qualification study.



F. Statistical Analysis

Means, sample standard deviations, and two-sided 95% t confidence intervals were calculated across the five target points. A paired t-test compared the before- and after-compensation errors at the same spatial points, and Cohen's dz was calculated as the mean paired decrease divided by the standard deviation of the paired decreases. Because n = 5 and no repeated-trial data were retained, the inferential statistics are exploratory and characterize consistency across sampled locations rather than production repeatability.

IV. Results

Table I reports the five paired point-level observations. The uncompensated errors ranged from 5.8 to 9.1 mm, and the compensated errors ranged from 1.7 to 2.6 mm. Every target point improved, with percentage reductions between 70.7% and 71.4%. Fig. 3 illustrates the physical before-and-after correction sequence; the images are illustrative, whereas the numerical evaluation is based on the measurements in Tables I and II.

Fig. 3(a) shows the marking tool after the initial positioning command, and Fig. 3(b) shows the tool after the correction command. The corresponding dataset-level mean displacement decreased from 7.40 mm before compensation to 2.14 mm after compensation. Individual P1-P5 values are reported in Table I rather than overlaid on the photographs because the photographs do not provide a traceable scale for independent measurement.

a b

Fig. 3. Execution of the visual correction: (a) tool position after the initial command and (b) tool position after the correction command. Across P1-P5, the mean measured error decreased from 7.40 to 2.14 mm.

For target point i, percentage error reduction was calculated as:

$$R = \left(\frac{e_{(before)} - e_{(after)}}{e_{(before)}} \right) * 100\%$$

where, e_before,i and e_after,i are the Euclidean errors measured before and after compensation at the same target point. Table I preserves the individual observations.

The mean error was 7.40 ± 1.35 mm before compensation and 2.14 ± 0.36 mm after compensation. The mean paired decrease was 5.26 ± 0.99 mm, with a 95% confidence interval of 4.04-6.48 mm. The exploratory paired test yielded t(4) = 11.92, p = 0.0003, and Cohen's dz = 5.33. These statistics indicate a consistent reduction across the five sampled locations, but they do not substitute for repeated trials at each point.

TABLE I. POINT-LEVEL POSITIONING ERROR BEFORE AND AFTER VISUAL COMPENSATION

Target point	Before compensation (mm)	After compensation (mm)	Error reduction (%)
P1	7.2	2.1	70.8
P2	5.8	1.7	70.7
P3	8.4	2.4	71.4
P4	6.5	1.9	70.8
P5	9.1	2.6	71.4
Mean	7.4	2.14	71.0

TABLE II. DESCRIPTIVE AND EXPLORATORY POINT-LEVEL STATISTICS ACROSS FIVE TARGET LOCATIONS

Quantity	Estimate	95% CI
Before compensation	7.40 ± 1.35 mm	5.72-9.08 mm
After compensation	2.14 ± 0.36 mm	1.69-2.59 mm
Paired decrease	5.26 ± 0.99 mm	4.04-6.48 mm
Paired test	t(4) = 11.92	p = 0.0003
Effect size	Cohen's dz = 5.33	Point-level

After correction, the electromagnetic tool was activated. The photograph below shows one resulting mark and demonstrates process feasibility. It is not a quantitative mark-quality test: the retained experiment does not include independent measurements of mark-center deviation, character dimensions, depth, edge quality, or repeatability (Fig. 4). Accordingly, marking quality is not used as evidence for the positioning claim.

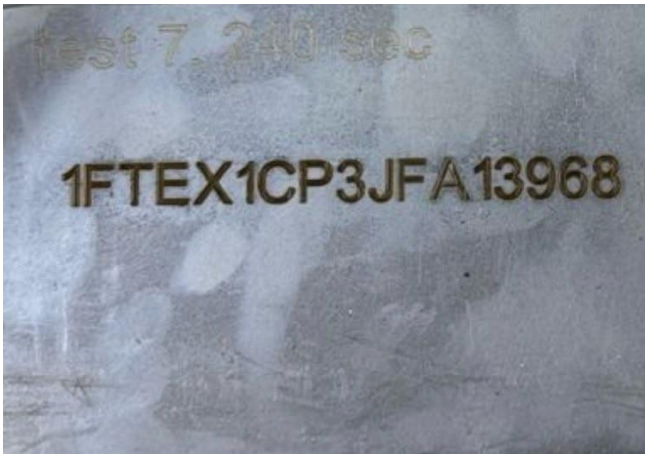


Fig. 4. Example mark produced after visual correction. The image demonstrates execution feasibility only; mark geometry was not measured quantitatively.

The available evidence therefore supports a narrow conclusion: one local translational correction reduced measured tool-to-target error at each of five tested sites. It does not establish orientation accuracy, camera-only measurement uncertainty, mark-quality repeatability, cycle-time overhead, or robustness to environmental changes.

V. DISCUSSION

Across the five target sites, compensation reduced mean error from 7.40 to 2.14 mm and produced a mean paired decrease of 5.26 mm. The narrow range of percentage reductions indicates similar relative behavior at the sampled sites. The point-level confidence interval excludes zero, and the exploratory paired test is consistent with a large reduction. Because only five site-level pairs were retained, these results should be interpreted as pilot evidence rather than an estimate of trial-to-trial repeatability.

The improvement is attributable to measuring the net residual displacement after the initial command. This timing allows one correction to incorporate the combined effect of localization, transformation, TCP, and manipulator errors present at that moment. The revised formulation also makes clear that camera-space displacement is rotated into the robot base frame before it is added to the TCP position. Direct addition without this transformation would be valid only if the camera and base axes were already coincident.

The approach reuses the camera already present in the marking cell, but this does not make the measurement metrologically independent. Published D455 characterizations show that depth error depends on range, surface inclination, and device behavior [47], [48]. The final 2.14 mm value therefore includes camera and registration uncertainty. The method should be described as low-cost visual compensation rather than as a replacement for traceable external metrology.

Table III positions the result against selected calibration and compensation studies. The numerical values are contextual because the studies use different robots, sensors, workspaces, and error definitions. Laser-tracker and learned models achieve smaller residuals but require calibration datasets and high-accuracy reference instruments. The proposed method uses one local RGB-D correction and addresses a less demanding marking setup. Its novelty is the integrated pre-marking sequence and explicit frame-consistent offset, not state-of-the-art absolute positioning accuracy.

TABLE III. CONTEXTUAL COMPARISON WITH SELECTED COMPENSATION METHODS

Study	Sensing and method	Reported result	Comparison notes
Ma et al. [10]	Laser tracker; non-kinematic and base-error model	Trajectory error -1.3231 to -0.1297 mm	Robotic milling; signed axis error
Jiang et al. [50]	Laser tracker; optimized neural network	Mean 0.8497 to 0.0490 mm	Global calibration and learning
Tao et al. [51]	Laser tracker; DE-DBN offline compensation	0.469 to 0.084 mm; 82.14%	Training data and traceable metrology
Li et al. [26]	Industrial camera, PLC, iterative correction	Accuracy within 0.231 mm	Different robot and repeated grasping task
Present pilot	D455 RGB-D; one local TCP correction	7.40 to 2.14 mm; 71.0%	Five marking sites; no trial-level repeats

The study has six principal limitations. First, the retained dataset contains only five spatial observations and no trial-level repetition series. Second, exact base-frame coordinates and robot joint configurations for P1-P5 were not archived, which limits workspace reproducibility. Third, the work uses one camera, robot, tool, and controlled workcell. Fourth, illumination, camera displacement, workpiece rotation, vibration, and larger workspace changes were not tested independently. Fifth, only translation was corrected; orientation and contact-normal error were not measured. Sixth, image-processing time, error-estimation time, correction-motion time, total added cycle time, and quantitative mark quality were not instrumented. These constraints preclude broad industrial generalization. A follow-up study should use an ISO 9283-informed repeated-point protocol, publish raw trials and target coordinates, validate camera and hand-eye uncertainty, add calibrated and alternative vision baselines, measure timing and mark geometry, and test environmental perturbations.

VI. Conclusion

This study presented a marking-specific, vision-based residual error correction for an AR4-MK3 robot. The method measures the target-to-tool displacement after the initial command, rotates that displacement from the camera frame into the robot base frame, and applies one translational TCP correction before marking. Across five target sites, mean error decreased from 7.40 ± 1.35 mm to 2.14 ± 0.36 mm. The mean paired decrease was 5.26 mm (95% confidence interval: 4.04-6.48 mm), and all sites improved by approximately 71%.

The result demonstrates feasibility under the tested configuration, not complete industrial validation. The study does not establish repeated-trial precision, rotational accuracy, camera metrological uncertainty, mark-quality repeatability, processing time, or robustness to environmental changes. Future work should report raw repeated measurements at documented workspace coordinates, compare calibrated and alternative vision baselines, quantify the full camera-to-robot uncertainty chain, measure orientation and mark geometry, and evaluate cycle time and robustness before broader deployment claims are made.

***Abstract*—The existing employment-prediction models overlook key challenges including panel-data endogeneity, cross-tier prediction unfairness, and year-on-year temporal distribution drift. To address these issues, this study proposes a novel deconfounded and fair employment-prediction framework, built upon panel stratification and a time-varying loss function within a DML-enhanced panel XGBoost architecture. From the Input-Process-Output (IPO) theoretical perspective, the raw dataset forms a ten-year balanced panel covering 30 universities over 2015-2024. After introducing a two-year lag for key predictors, the analytical sample spans 2017-2024 and yields 240 valid observations. Double Machine Learning (DML) mitigates confounding-driven bias to produce conditionally de-confounded associative estimates under explicitly stated identification assumptions for this observational panel dataset. Meanwhile, the time-varying loss function alleviates cross-tier prediction disparities amid temporal-distribution shifts, and panel stratification further reduces prediction biases across university subgroups. The evaluation suite includes baseline-model comparisons, ablation studies, and robustness analyses. Experimental results under the rolling-origin evaluation protocol demonstrate that the proposed method achieves lower prediction error and improved subgroup fairness relative to benchmark models. SHAP-based interpretability analysis reveals prominent nonlinear threshold and interaction effects between teaching quality and per-capita funding.**

***Keywords*—Employment policy; graduate employment prediction; enhanced XGBoost; time-sequence fairness; DML**

I. Introduction

This study evaluates graduate employment rates as one of the most important indicators of Chinese universities' performance and educational quality. Given the increase in the number of students and changing labor markets, linear modeling fails to identify the complex nonlinear relationship between institutional variables and their employment outcomes. China's gross enrollment ratio increased from 40% (2015) to 59.6% (2024), and universities were stratified into three levels: Double First-Class, provincial comprehensive, and vocational/applied universities. Large differences among the tiers in terms of institutional resources, student characteristics, and employment rates prevent the development of generalized models of prediction.

In recent years, employment prediction analysis has shifted from classical statistical techniques to machine learning algorithms such as MLR, RF, GBM, and XGBoost [2, 4, 15]. The latter algorithms prevail due to the nonlinear nature and high generalization ability [2, 22]; however, there are at least three significant drawbacks of currently available employment prediction tools.

First, most of the models use a single loss function for all tiers of institutions. As a result, there is estimation bias towards elite universities and significantly larger prediction error for lower-tier institutions. This imposes great barriers to achieving predictive fairness, which has become an essential factor for social decision-making in ML [21]. Causal fairness is introduced to overcome the historical biases [13, 26]; however, only a few papers include fairness criteria in employment rate prediction based on hierarchical panel data.

Second, hyperparameter tuning for small educational panel datasets is usually done via grid and random search, resulting in overfitting and instability in the output. The situation differs greatly from industrial-scale big data due to the necessity of higher stability.

Third, the importance of the interpretability of the model is poorly incorporated into the IPO framework. SHAP technique is widely used; however, there are few attempts to prove cross-fold stability. Moreover, unstable importance cannot be used to support decision-making. Most models focus on correlation rather than causation [10].

Firstly, in this study, DML de-confounding methodology is integrated into the stratified panel XGBoost method so as to address potential confounding and regularization-related bias, enabling DML-based effect estimation under stated identification assumptions [1, 5]. To handle the three-tier university ranking structure and the decade-wise temporal change in employment data in China, time-varying fair loss functions in terms of static subgroup stratification are developed in this research. The DML-based stratified panel

*Corresponding author. Email ID - ting.tintin@researcher.unitar.my

XGBoost model with time-varying loss functions with stratification and Bayesian hyperparameter tuning is developed based on the ten years of balanced panel data of 30 universities. SHAP and nonlinear analysis stability tests are employed to develop tiered policy recommendations.

The main contributions of this study are three-fold. Firstly, this study integrates DML de-confounding methodology into the stratified panel XGBoost method to reduce confounding-related bias under explicit identification assumptions for observational panel data. The data-driven time-varying fair-loss function assigns tier-adaptive error penalties to mitigate temporal distribution shift and delivers consistent error reduction for disadvantaged Tier-3 universities both in cross-validation and unseen future hold-out periods. Third, this study combines time fixed effects, Bayesian optimization, and cross-validation SHAP, whose coefficient of variation is reduced by 46.3%, and identifies the threshold effects and interaction effects.

II. Literature Review

This section reviews prior studies on graduate employment prediction, XGBoost, model interpretability, DML causal inference, causality-aware fairness, and the IPO framework, and summarizes key research gaps.

A. Employment Prediction in Higher Education

Early studies on graduate employment prediction used linear regression to assess linear associations between university factors and outcomes [24, 28], yet linear specifications miss nonlinear interactions. Later studies adopted ensemble algorithms (RF, GBM) for better accuracy [20, 23], addressed class imbalance [14], or applied deep learning to explain cross-institutional disparities [16].

However, most existing work treats universities as homogeneous, causing systematic bias against mid-tier and vocational institutions [18]. Even tier-grouped analyses by Wang et al. (2025) overlook temporal shifts and endogenous confounders in longitudinal panel data [12, 28], leaving a notable research gap.

B. XGBoost Model and Its Deficiencies

XGBoost improves gradient boosting via second-order approximation and regularization [4], offering higher efficiency and generalization [25]. It has been widely applied to academic assessment and employment prediction [2, 22], proving effective for nonlinear educational data. However, vanilla XGBoost assigns uniform loss weights across samples, which fails for hierarchical panel datasets. Small sample sizes cause unstable outputs, and equal weighting magnifies errors for underrepresented subgroups [8]. Few improved versions restructure the loss function to reflect the institutional hierarchy.

C. Interpretability of Machine Learning Models

SHAP has become the primary method for interpreting black-box ML models, offering Shapley-based feature importance [15, 17]. However, SHAP rankings can be unreliable under high multicollinearity—common in educational data [27](Sundararajan & Najmi, 2020). Most higher education studies use static one-off SHAP without testing cross-fold stability [9, 22]. This weakness undermines evidence-based policy and remains unresolved in employment forecasting [11].

D. Double/Debiased Machine Learning (DML) for De-Confounded Associative Estimation

This study leverages Double/Debiased Machine Learning (DML), which combines ML flexibility with econometric identification to mitigate potential confounding and regularization-related bias under given identification assumptions [5]—suitable for small social-science panels [1]. Recent DML extensions incorporate fixed effects for panel inference [6] and offer protocols to prevent over-regularization [7]. Despite these methodological advances, DML has seldom been adopted in graduate employment prediction, even though panel endogeneity persists as a prevalent and unsolved challenge in this research field.

E. Causality-Based Fair Machine Learning

Fairness is now a fundamental requirement for ML in social decision-making, as algorithmic bias can reinforce educational resource inequities [3, 21]. Early work on static group parity has evolved into counterfactual and causal fairness frameworks to address historical dataset biases [13, 26], with unified benchmarks facilitating comparisons [19]. Recent studies explore multi-group fairness in educational forecasting [30] and temporal fairness preservation [29]. Yet no existing work designs time-varying adaptive fairness constraints for long-term educational panels to address yearly distribution shifts—a gap this study fills.

F. IPO Framework and Research Gaps

Three research gaps directly correspond to the core innovations of this study. First, traditional models ignore panel endogeneity. To address this issue, this study incorporates DML debiasing into the XGBoost framework to realize rigorous DML-based debiased association estimates. Second, static fairness mechanisms fail to accommodate temporal distribution drift. Accordingly, this study develops a time-varying fair loss function to implement dynamic subgroup fairness constraints. Third, existing interpretability results lack stability testing and cross-tier nonlinear threshold exploration. This study therefore adopts cross-validated SHAP analysis and stratified nonlinear effect identification to provide quantitative evidence for tier-differentiated policymaking.

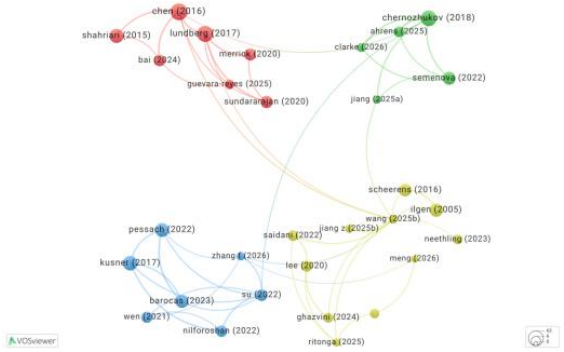

Fig. 1. Thematic clustering network of cited references generated by VOSviewer.

As illustrated in Fig. 1, the relevant literature falls into four thematic clusters: XGBoost and interpretability, DML causal inference, algorithmic fairness, and IPO-based employment research. Most studies remain siloed within single clusters, leaving a gap for an integrated framework combining de-confounding bias mitigation, fairness constraints, and stratified prediction, which motivates the methodology proposed below.

III. METHODOLOGY

A. Overall Framework

The overall architecture of the proposed DML-augmented stratified panel XGBoost framework is illustrated in Fig. 2.

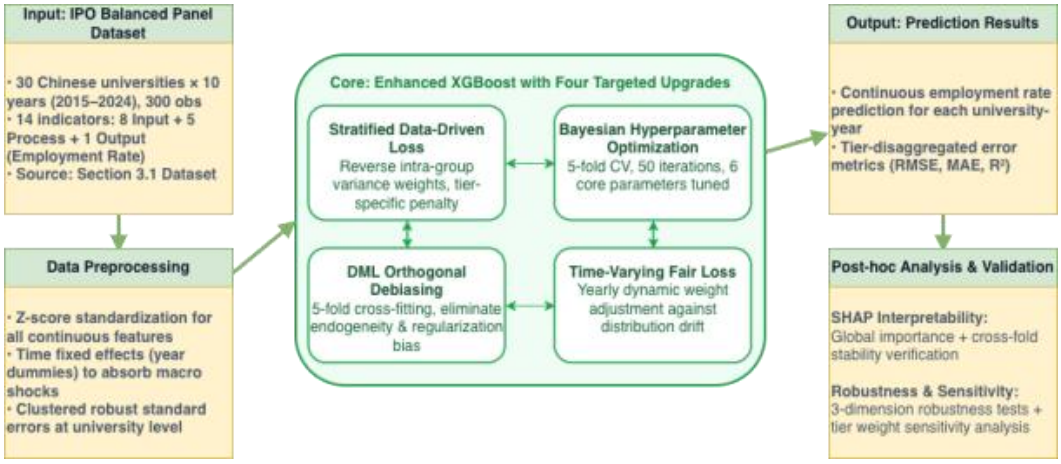

Fig. 2. Overall architecture of the proposed DML-augmented stratified panel XGBoost framework.

This framework integrates double debiased machine learning, stratified panel XGBoost with time-varying fair loss, and cross-fold SHAP stability interpretation. First, DML is applied to reduce confounding-related bias under explicit identification assumptions for observational university panel data. Second, the stratified weighted loss function imposes subgroup-aware penalty terms to reduce prediction bias across university tiers. Finally, cross-fold SHAP stability analysis is implemented to produce reliable, policy-oriented feature interpretation for different university subgroups.

B. Dataset

In the current study, the original balanced panel includes 30 Chinese universities (ten universities for each tier) ranging from 2015 to 2024, thus including 300 raw data points collected from the university official yearbooks [28]. The following 14 input-process variables are formed using an entropy-weighted method, with graduate employment rate (ER) being the dependent variable in the IPO framework.

As for independent variables, there are two key predictors (INF, PCF) introduced with a lag of two years $(t − 2)$. The two-year lag eliminates the first two years of observations for each university (2015 and 2016), since no data are available for those initial years as $(t − 2)$. Thus, the final sample includes 240 observations (30 universities × 8 years, 2017-2024).

Table I contains a summary of variables, their classification in the IPO framework, descriptive statistics, and their definitions.

TABLE I. VARIABLE DEFINITIONS AND DESCRIPTIVE STATISTICS

Variable	IPO Category	Mean	Std	Description
ENR	Input	28542.3	12456.7	Enrollment size
INF	Input	0.782	0.124	Infrastructure capacity
PCF	Input	12.45	4.32	Per Capita Funding (10k RMB)
F	Input	2456.7	892.3	Total Funding Income (Million RMB)
AREA	Input	125.6	45.2	Campus Area (Hectare)
SAL	Input	8.76	2.34	Average Faculty Salary (10k RMB)
QS	Input	45.6	12.3	QS University Ranking
TQ	Process	0.824	0.098	Entropy-weighted composite of course evaluation pass rate, teaching achievement awards and thesis quality; sourced from university annual quality reports
ME	Process	0.765	0.112	Composite of ideological course coverage, off-campus practice hours and social service projects; from official annual reports
CC	Process	0.687	0.134	Count of industry-university cooperation projects and joint training bases; from provincial education department bulletins
MP	Process	0.798	0.087	Internal governance evaluation score and administrative efficiency index; from university annual work reports
APU	Process	0.654	0.102	Weighted average of discipline competition awards and academic retention rate; from teaching quality reports
EL	Input	1.23	0.45	Regional Economic Level
ER	Output	0.876	0.078	Employment Rate (Target)

This study lags two core input variables (INF, PCF) by two years to capture delayed DML-based de-biased association estimates between predictors and graduate employment outcomes. Panel pretests (IPS unit root and Hausman) are reported in Table II. All variables pass stationarity at 1%, ruling out spurious regression. The Hausman test supports time fixed effects. Annual dummies for 2015–2024 absorb common macroeconomic shocks, and university-clustered robust standard errors account for within-institution residual correlation.

TABLE II. PANEL UNIT ROOT TEST AND HAUSMAN TEST RESULTS

Variable	IPS Statistic	P-value	Stationarity	Statistic	P-value
ENR	-2.846	0.002	Stationary	28.742	0.001
INF	-3.125	0.001	Stationary	—	—
PCF	-2.753	0.003	Stationary	—	—
F	-2.688	0.004	Stationary	—	—
AREA	-2.591	0.005	Stationary	—	—
SAL	-2.812	0.002	Stationary	—	—
QS	-2.476	0.007	Stationary	—	—
TQ	-3.015	0.001	Stationary	—	—
ME	-2.944	0.002	Stationary	—	—
CC	-2.701	0.004	Stationary	—	—
MP	-2.869	0.002	Stationary	—	—
APU	-2.633	0.004	Stationary	—	—
EL	-2.518	0.006	Stationary	—	—
ER	-3.207	0	Stationary	—	—

Note: The IPS test is used for the panel unit root test. All variables are stationary at level ($p < 0.01$). Hausman test rejects the null hypothesis ($p < 0.01$), supporting the use of time-fixed effects. Only "ENR" Decision on Time-fixed effects.

The Hausman test yields, strongly rejecting the null hypothesis and supporting the adoption of time-fixed effects in the model.

Rolling-origin temporal validation and university-group blocking setup for panel data.

After applying the two-year lag for INF and PCF, the analytical panel in this study spans 2017–2024. This study adopts rolling-origin temporal validation for outer-loop model performance assessment. The training origin is fixed at 2017 and expands chronologically forward as Table III.

TABLE III. ROLLING-ORIGIN TEMPORAL-VALIDATION SPLIT SETTINGS

Train set years	Validate year
2017-2019	2020
2017-2020	2021
2017-2021	2022
2017-2022	2023
2017-2023	2024

Note: The above rolling-origin cross-validation serves as an inner-loop procedure for hyperparameter tuning and DML nuisance-model fitting. Separate out-of-sample rolling-origin unseen-period hold-out tests for future-period generalization are reported in Section IV-A.

In every outer-loop iteration, only strictly historical observations before the validation year are accessible. No future-year records are used for preprocessing, hyperparameter tuning, DML estimation, or model fitting, eliminating temporal look-ahead leakage.

Within each fixed historical training window, DML panel-level cross-fitting further applies university-group blocking (group-aware cross-fitting): all time-series records belonging to the identical university ID are kept within a single fold unit. Observations from one university are never split across different folds, which prevents within-unit information leakage during nuisance-model estimation. Bayesian hyperparameter optimization is also nested inside each outer-loop training window and adopts this university-blocked inner splitting.

C. Enhanced XGBoost Model

Based on panel pretests, this study constructs an improved XGBoost framework with four targeted enhancements. Standard XGBoost penalizes prediction loss and structural complexity [4; Chen & Guestrin, 2016], but its uniform loss weighting biases predictions across heterogeneous tiers [8]. The proposed upgrades address four dimensions: stratified data-driven loss design, Bayesian tuning, DML-based endogeneity correction, and time-varying fairness constraints.

$$Obj = \sum_{i=1}^{n} l\,(y_i, \hat{y}_i) + \sum_{k=1}^{K} \Omega\,(f_k) \qquad (1)$$

In Eq. 1, ι is the loss function, y_i is the true value, $\hat{y}_i$ is the predicted value, and Ω is the regularization term. Nevertheless, conventional XGBoost adopts a universal loss function that assigns identical weight to all observations, making it ill-suited for hierarchically stratified higher education datasets.

In Eq. (1), l denotes the loss function, y_i is the true value, $\hat{y}_i$ is the predicted value, and Ω denotes the regularization term.

1) Stratified data-driven loss function: This study confirms significant employment disparities across tiers via one-way ANOVA ($F=18.74$, $p<0.001$). Tier-specific weights are calculated from the inverse of training-set within-group variance and normalized relative to Tier 1. The detailed derivation is defined in Eq. (2)–(5):

$$\hat{\sigma}^2_{g,\text{train}} = \frac{1}{n_g - 1} \sum_{i \in g} (y_i - \bar{y}_g)^2 \qquad (2)$$

Eq. (2): $\hat{\sigma}^2_{g,\text{train}}$ denotes the estimated within-group variance for subgroup g calculated only on the training dataset; n_g is the sample size of group g, y_i is the target value for sample i, and $\bar{y}_g$ is the group mean.

$$\tilde{\omega}_g = \frac{1}{\hat{\sigma}^2_{g,\text{train}} + \epsilon} \qquad (3)$$

Eq. (3): $\tilde{\omega}_g$ is the raw unnormalized group weight, ϵ is a small constant to avoid division by zero.

$$\omega_g = \frac{\tilde{\omega}_g}{\tilde{\omega}_{\text{Tier1}}} \qquad (4)$$

Eq. (4): ω_g is the final normalized subgroup weight, scaled relative to Tier 1 baseline.

$$\mathcal{L}_{\text{stratified}} = \frac{1}{N} \sum_{i=1}^{N} \omega_{g_i}\, l(y_i, \hat{y}_i) + \Omega(f) \qquad (5)$$

Eq. (5): Final stratified loss function, $l(y_i, \hat{y}_i)$ is the sample-wise prediction loss, $\Omega(f)$ is the model regularization term, N denotes the total training samples.

The above stratified loss function entails different levels of penalties for errors for subgroups within the university. Group-level penalty values are pre-computed from within-group training-set variances and are not manually tuned to minimize prediction error.

2) Bayesian hyperparameter optimization: Grid and random search methods may exhibit unstable performance in small educational panel datasets [25]. This study utilizes Bayesian hyperparameter optimization nested inside each rolling training window with inner chronological validation splits and 50 search iterations to calibrate six key hyperparameters within pre-specified continuous and discrete search spaces. Hyperparameter tuning only accesses historical data, without using any future-year panel observations. Optimal hyperparameter configurations are listed in Table IV; the probabilistic surrogate model of Bayesian search reduces redundant trials and suppresses small-sample overfitting risks.

TABLE IV. BAYESIAN OPTIMIZATION HYPERPARAMETERS AND OPTIMAL VALUES

Hyperparameter	Description	Search Space	Optimal Value
learning_rate	Step size for gradient updates	0.01–0.30	0.12
max_depth	Maximum depth of a decision tree	3–8	5
min_child_weight	Minimum sum of instance weight for a child	1–6	3
subsample	Subsample ratio of training instances	0.6–1.0	0.82
colsample_bytree	Subsample ratio of features for each tree	0.6–1.0	0.78
n_estimators	Number of decision trees	100–500	240

Note: Bayesian optimization is nested within each rolling-origin training window and uses university-group blocked inner cross-validation with 50 search iterations to ensure stability for small-sample educational panel data. No future-year data enters tuning procedures.

3) DML endogeneity debiasing module

a) Causal estimand and identification setup: The study defines the working model at the panel level for the outcome and treatment variables to describe the de-biasing procedure based on DML. It is worth mentioning that the models described below define the estimand for this study as part of the conditional association analysis given the observed covariates, as the causal assumptions are not fully confirmed.

Outcome model specification in Eq. (6):

$$Y_{it} = \theta D_{it} + g(X_{it}) + \alpha_i + \lambda_t + \varepsilon_{it} \quad (6)$$

where, Y_{it}: graduate employment rate for university i in year t; D_{it} : treatment variable (either teaching quality TQ or per-capita funding PCF); X_{it} : vector of other observed time-varying covariates; α_i : university-level fixed effect; λ_t : year fixed effect; θ: the target parameter of interest in this study (interpreted as a DML-based de-biased associative coefficient conditional on observed controls, not a definitive causal effect); ε_{it}: residual disturbance term.

Treatment nuisance model for the endogenous predictor in Eq. (7):

$$D_{it} = m(X_{it}) + \alpha_i^D + \lambda_t^D + v_{it} \quad (7)$$

where, $m(\cdot)$ is the nuisance predictive function for treatment, α_i^D / λ_t^D are unit- and time-fixed effects for the treatment equation, and v_{it} is the treatment residual.

b) Panel-level cross-fitting and orthogonal score computation: For DML internal panel-level cross-fitting for nuisance-parameter estimation, this study adopts university-group blocked K-fold splitting within each fixed historical training window, instead of naive observation-level random splitting. All panel records from the same university are assigned entirely to one fold; individual university time-series are never fragmented across folds. This group-aware blocking mitigates within-unit information leakage when estimating nuisance functions $g(\cdot)$ and $m(\cdot)$. Importantly, this DML-internal fold partition is separate from the chronological rolling-window cross-validation used for final model performance evaluation. Under the rolling-window evaluation scheme, nuisance model fitting and target-parameter estimation are always restricted strictly to historical observations; future panel records are completely unseen during training to prevent temporal leakage.

The orthogonal score for the target parameter θ is constructed based on residualized outcome and treatment in Eq. (8):

$$\psi_i(\theta; \hat{g}, \hat{m}) = \widehat{v_{it}} \cdot (Y_{it} - \hat{g}(X_{it})) - \theta D_{it} \quad (8)$$

where, Eq. (8) $\widehat{v_{it}} = D_{it} - \hat{m}(X_{it})$ denotes the residual from the treatment nuisance model. The estimating equation solves $\mathbb{E}\backslash\psi_i(\theta; \hat{g}, \hat{m}) = 0$ to obtain $\hat{\theta}$, which are reported in Table V as DML-Based Debiased Association Estimation Results.

Important caveat: The orthogonal score only removes confounding from observed variables and fixed effects. Unobserved time-varying confounders cannot be eliminated by this procedure, which limits causal interpretability $\hat{\theta}$.

c) Output of de-confounded associative coefficients: This objective weighting penalizes mid- and low-tier forecast errors without manual adjustment, effectively reducing subgroup prediction bias. The estimated effects of the two focal treatments are reported in Table V.

TABLE V. DML-BASED DEBIASED ASSOCIATION ESTIMATION RESULTS

Variable	Coefficient (β)	Standard Error	95% Confidence Interval	p-value
Teaching Quality (TQ)	0.214	0.042	[0.132, 0.296]	<0.001
Per Capita Funding (PCF)	0.147	0.035	[0.078, 0.216]	<0.01

4) Time-varying temporal fair loss: This study replaces fixed stratified weights with time-varying adaptive penalties [26, 30], recalculating subgroup variances yearly and updating loss weights to maintain fairness amid temporal distribution drift.

This work proposes the use of dynamic loss penalization based on adaptive penalties [26, 30], where subgroup variance is recalculated each year, along with loss weights being updated to preserve balance despite temporal changes in distribution. In the rolling origin validation procedure, subgroup variance is estimated each year based only on training set samples. Raw weights are obtained through inverse group variance calculation and normalization in relation to Tier 1 ($\omega_g = \tilde{\omega}_g/\tilde{\omega}_{\text{Tier1}}$).

Yearly subgroup residual-variance values, raw inverse-variance weights, and final normalized loss weights are provided in Appendix Table XVI for each university tier from 2017 to 2024. The normalized loss weight of Tier 1 is fixed at 1.00 as the baseline reference. The annual variations in subgroup residual variances were numerically linked to the variations in the normalized loss weights, while the results for the unseen periods in Table XII and Table XIII demonstrate that the adaptive adjustments led to reduced prediction errors compared to the static stratified loss. Fig. 3 visualizes the temporal evolution of normalized tier-specific loss weights across 2017–2024.

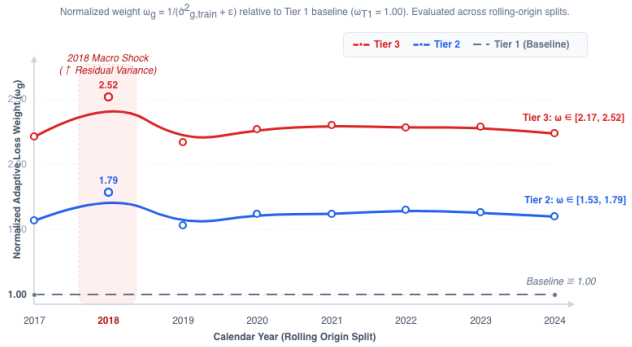

Fig. 3. Temporal evolution of normalized tier-specific loss weights.

Note: Natural cubic spline interpolation through empirical normalized weights. Tier 3 consistently receives the highest loss penalty $\omega_{T3} > \omega_{T2} > 1.00$ corroborating localized volatility propagation reported in Fig. 6 (a).

According to Appendix Table XVI and Fig. 3, the variation of residual variances within each subgroup and their loss weights is not constant from year to year. The above evidence proves the presence of temporal distribution shift in the universities and necessitates the use of loss function adaptation depending on time.

D. Evaluation Metrics

This task is continuous regression forecasting for employment rate, so three standard cross-validation regression metrics (RMSE, MAE, R^2) are adopted in Eq. (9)–(11). All regression metrics are aggregated and averaged across multiple rolling-window evaluation folds to ensure stability, with chronological splitting preventing temporal look-ahead leakage. Discrete classification indicators (Precision, Recall, F1) are excluded, as binning continuous employment rates introduces artificial evaluation bias. Note that input predictor features are z-score standardized for model fitting; nevertheless, all evaluation metrics RMSE, MAE, and R^2) are computed on the original unstandardized outcome scale of graduate employment rate (ER). The target variable itself is not standardized.

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (9)$$

$$\text{MAE} = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \quad (10)$$

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2} \quad (11)$$

All evaluation results are aggregated across rolling-origin temporal-validation folds to ensure stability, with chronological splitting preventing temporal look-ahead leakage.

TABLE VI. GROUP-WISE FAIRNESS METRICS COMPARISON (PROPOSED ENHANCED XGBOOST VS. VANILLA MSE-LOSS XGBOOST)

Fairness Metric	Symbol	Enhanced XGBoost (Customized Stratified Loss)	XGBoost (Uniform MSE Loss)
Tier-1 RMSE	RMSE 1	0.0198	0.0205
Tier-2 RMSE	RMSE 2	0.0271	0.0312
Tier-3 RMSE	RMSE 3	0.0325	0.0387
Tier-1 MAE	MAE1	0.0142	0.0149
Tier-2 MAE	MAE2	0.0196	0.0227
Tier-3 MAE	MAE3	0.0237	0.0282
Worst-group RMSE	($RMSE_w$	0.0325	0.0387
RMSE gap	($RMSE_{ga}$	0.0127	0.0182
Relative disparity (RMSE)	(RD_{RMSE}	1.64	1.89
MAE gap	(MAE_{gap}	0.0095	0.0133
Calibration slope	(β_{cal})	0.942	0.881
Calibration intercept	(α_{cal})	0.0041	0.0086

Note: All measurements were performed using rolling-origin temporal-validation folds. MAE was calculated directly from the absolute prediction errors within each university tier. The parameters of calibration were calculated using regression of the actual employment rate against the predicted value.

Fairness Measures: In order to measure subgroup fairness in prediction for each of the three university tiers, this study has explicitly formulated a set of group-specific fairness measures (results in Table VI), instead of simply considering only Tier-3 error. The measures capture performance, maximum loss, group-wise prediction errors, ratios of errors, and prediction calibration.

1) Group-wise RMSE / MAE: RMSE1, RMSE2, RMSE3 and MAE1, MAE2, MAE3 denote RMSE and MAE computed separately for Tier 1, Tier 2, Tier 3 university subgroups.

2) Worst-group RMSE: $\text{RMSE}_{\text{worst}} = \max(\text{RMSE}_1, \text{RMSE}_2, \text{RMSE}_3)$: prediction error of the most disadvantaged subgroup.

3) RMSE gap: $\text{RMSE}_{\text{gap}} = \max(\text{RMSE}_1, \text{RMSE}_2, \text{RMSE}_3) -$

$\min(\mathrm{RMSE}_1, \mathrm{RMSE}_2, \mathrm{RMSE}_3)$: absolute difference between largest and smallest subgroup RMSE.

4) Relative disparity (RMSE): $\mathrm{RD}_{\mathrm{RMSE}} = \frac{\max(\mathrm{RMSE}_1, \mathrm{RMSE}_2, \mathrm{RMSE}_3)}{\min(\mathrm{RMSE}_1, \mathrm{RMSE}_2, \mathrm{RMSE}_3)}$: ratio of worst-group to best-group RMSE.

5) MAE gap: $\mathrm{MAE}_{\mathrm{gap}} = \max(\mathrm{MAE}_1, \mathrm{MAE}_2, \mathrm{MAE}_3) - \min(\mathrm{MAE}_1, \mathrm{MAE}_2, \mathrm{MAE}_3)$: absolute MAE difference across subgroups.

6) Calibration: The calibration slope and intercept are estimated by regressing true employment-rate outcomes against model-predicted values.

Lower values for worst-group RMSE, RMSE difference, relative difference, and MAE difference show less prediction differences between tiers, while better calibration occurs when the slope approaches 1, and the intercept approaches 0.

E. SHAP Stability Interpretability

This study applies SHAP to quantify marginal feature contributions and conducts cross-fold stability checks across five group-blocked folds used for SHAP stability assessment to filter volatile explanations, ensuring credible interpretability for policy [9, 11, 15, 22]. The theoretical SHAP value formulation is defined in Eq. (12)

$$\phi_j = \sum_{S \subseteq F \setminus \{j\}} \frac{|S|!(|F|-|S|-1)!}{|F|!} [f(S \cup \{j\}) - f(S)] \quad (12)$$

Eq. 12: F denotes the complete set of predictive variables, S represents a subset of features, and f(·) corresponds to the model prediction function.

SHAP values satisfy the consistency axiom: if the model is updated such that a feature's marginal predictive contribution increases, its corresponding Shapley value will rise accordingly. Beyond calculating global feature importance, this study further examines the stability of SHAP estimations across different cross-validation folds to ensure reliable and robust model interpretation.

IV. Experiments and Results

All input predictor features are preprocessed using z-score standardization before model training. The target graduate employment-rate (ER) outcome variable remains on its original 0-1 scale and is not standardized. To avoid temporal leakage for panel time-series data, time-aware rolling-window cross-validation is adopted for overall model performance evaluation instead of random stratified sample-level folding. This chronological splitting strictly ensures that future-year observations never appear in the training set, so that robustness can be assessed without look-ahead bias.

A. Experimental Protocol

In this subsection, this study briefly describes all experimental execution settings and reproducibility settings used throughout the empirical analyses; definitions of mathematical models and their formulae are kept in Section III Methodology.

1) Temporal split approach: This study adopts two different approaches for chronological evaluations. Firstly, this study uses rolling origin outer loop temporal validation for model performance evaluation. The training origin begins in 2017 and proceeds in a chronological fashion, treating every consecutive calendar year as the validation year. Secondly, separate unseen period hold-out evaluation is performed for out-of-sample generalization purposes, using entire future years as completely unseen periods.

2) University group awareness for DML inner-loop cross-fitting: For every fixed training window of history used for DML nuisance model estimation, this study performs K-fold splitting with university group awareness. This study assigns all records with the same university institution entirely to one fold. Observations related to each university group will not be split among different folds to avoid any possible within-unit information leakage while estimating nuisance functions. Inner-loop fold splitting is independent of outer-loop rolling-origin performance evaluation.

3) Complete separation of training and test windows and absence of temporal leakage principle: Strict chronological separation is applied: any observation from validation or hold-out years is completely out of view during any training-related step. Any record from future years is forbidden to leak into any part of preprocessing, hyper-parameter search, DML nuisance model estimation, and subgroup loss weighting calculation.

4) Random seed setting: Deterministic single-run results are achieved using fixed random seeds for all model evaluations described in this study. As it is stated in the robustness section, statistical uncertainty was assessed using 30 independent random-seed repetitions, with mean performance, standard deviation, and 95% confidence intervals reported for the principal evaluation metrics.

5) Hyper-parameter optimization approach: Bayesian hyper-parameter optimization is performed inside each rolling origin training window. Only data from the historical training split is used both for hyper-parameter search and inner-validation; no data from the validation set and hold-out set are used to perform hyper-parameter optimization.

6) Summary of anti-leakage constraints: All crucial steps, such as feature pre-processing scaling, Bayesian hyper-parameter optimization, DML cross-fitting nuisance estimation, and subgroup loss weights calculation, are performed only on the data from the current training window. Validation and hold-out samples do not participate in any of these fitting-oriented calculations.

7) Limitation of rolling-origin temporal-validation folds: Rolling-origin temporal-validation folds are not statistically independent because they share overlapping training-set time windows. To address this issue, this study has resorted to the use of 30 randomly seeded repetitions together with blocked multi-year temporal hold-out and leave-one-university-out cross-validation.

B. Baseline Model Comparison

Table VII summarizes regression performance metrics (RMSE, MAE, R^2) of classical statistical and ensemble baselines, standard XGBoost, and the proposed DML-augmented stratified panel XGBoost with time-varying fair loss.

TABLE VII. PERFORMANCE COMPARISON OF DIFFERENT BASELINE MODELS

Model	RMSE	MAE	R^2
Multiple Linear Regression	0.0452	0.0367	0.412
Random Forest	0.0387	0.0302	0.536
Gradient Boosting Machine	0.0312	0.0245	0.604
Standard XGBoost	0.0284	0.0215	0.641
Enhanced XGBoost	0.0264	0.0198	0.682

Note: All evaluation metrics (RMSE, MAE, R^2) are computed on the original unstandardized graduate-employment-rate outcome scale. Input predictor features are z-score standardized for model training; the target variable ER retains its original scale and is not standardized. Metrics are aggregated over rolling-origin temporal-validation folds.

This study outperforms all benchmark models on the three evaluation metrics (Table VII). Overall RMSE drops by 7.04%, and R^2 rises by 14.89% compared with vanilla XGBoost, balancing prediction accuracy with group-fairness performance. The stratified dual-objective loss prioritises lower-tier universities, enhancing its relevance for tier-differentiated governance. Performance improvements stem from fixed-effects specification, Bayesian hyperparameter tuning, DML orthogonal debiasing, and tier-aware fairness constraints.

C. Ablation Study of Core Modules

To quantify the individual contribution of each component and verify the above inference, two rounds of ablation experiments are conducted to test the static modules, DML debiasing, and time-varying fair loss separately.

1) Basic module ablation (static framework components): Five comparative model configurations sequentially add Bayesian optimization, stratified custom loss, DML debiasing, and time-varying fair-loss modules to isolate each component's incremental performance contribution, with Tier-3 RMSE as one key subgroup indicator; full multi-dimensional fairness evaluation follows the criteria defined in Section III-D and Table VI, and result shown in Table VIII.

TABLE VIII. ABLATION EXPERIMENTAL RESULTS OF ENHANCED XGBOOST

Model Configuration	Overall RMSE	Tier 3 RMSE	R^2
Standard XGBoost	0.0284	0.0387	0.641
XGBoost + Bayesian optimization	0.0271	0.0362	0.66
XGBoost + Stratified custom loss	0.0275	0.0325	0.652
XGBoost + Stratified custom loss + DML debiasing	0.0272	0.0316	0.668
Enhanced XGBoost (Stratified loss + DML + Time-Varying Fair Loss, Proposed)	0.0264	0.0312	0.682

Note: All evaluation metrics (RMSE, MAE, R^2) are computed on the original unstandardized graduate-employment-rate outcome scale. Input predictor features are z-score standardized for model training, but the target variable ER retains its original scale for performance evaluation.

Bayesian optimization primarily suppresses training volatility and improves generalization stability, while the stratified dual-objective loss drastically narrows prediction bias for vocational Tier 3 universities. Combining both modules yields additive performance improvements without mutual offsetting.

All performance gains that are incremental are summarized in Table IX. It clearly specifies the baseline configuration, metric, change, and evaluation split for each of the rows, leaving no doubt about what is compared to what.

TABLE IX. CONSOLIDATED PERFORMANCE CHANGES ACROSS MODEL COMPONENTS

Comparison	Metric	Baseline Configuration	Proposed Configuration	Absolute Change	Relative Reduction	Evaluation Split
Bayesian tuning	Overall RMSE	Standard XGBoost	XGBoost + Bayesian optimization	−0.0013	−4.58%	Rolling-origin temporal-validation folds
Static stratified custom loss	Tier3 RMSE	Standard XGBoost	XGBoost + Stratified custom loss	−0.0062	−16.02%	Rolling-origin temporal-validation folds
Add DML debiasing	Overall RMSE	XGBoost + Stratified custom loss	XGBoost + Stratified custom loss + DML debiasing	−0.0003	−1.09%	Rolling-origin temporal-validation folds
Add time-varying fair loss	Overall RMSE	XGBoost + Stratified custom loss + DML debiasing	Full Enhanced XGBoost (all modules)	−0.0008	−2.94%	Rolling-origin temporal-validation folds
Add time-varying fair loss	Tier3 RMSE	XGBoost + Stratified custom loss + DML debiasing	Full Enhanced XGBoost (all modules)	−0.0004	−1.27%	Rolling-origin temporal-validation folds
Time-varying vs static loss (unseen future)	Overall RMSE	Static stratified loss	Time-varying fair loss	−0.0016	−5.65%	Unseen-period hold-out (2022)
Time-varying vs static loss (unseen future)	Tier3 RMSE	Static stratified loss	Time-varying fair loss	−0.0028	−8.09%	Unseen-period hold-out (2022)

Note: Negative values indicate improved performance (errors decrease). The rolling-origin temporal validation is similar to the inner-loop cross-validation, while the hold-out validation in the unseen period makes use of out-of-sample future data that are unseen in the training process. Figures have been computed from Table VIII (ablation) and Table XI (hold-out test). Relative reduction (%) = (Proposed − Baseline) / Baseline * 100%.

2) Advanced innovation ablation (DML and time-varying fair loss): To verify the incremental value of this study's two frontier innovations, two extended model variants are constructed based on the static stratified XGBoost baseline: 1) static XGBoost integrated with DML debiasing; 2) the complete proposed framework equipped with DML and time-varying fair loss.

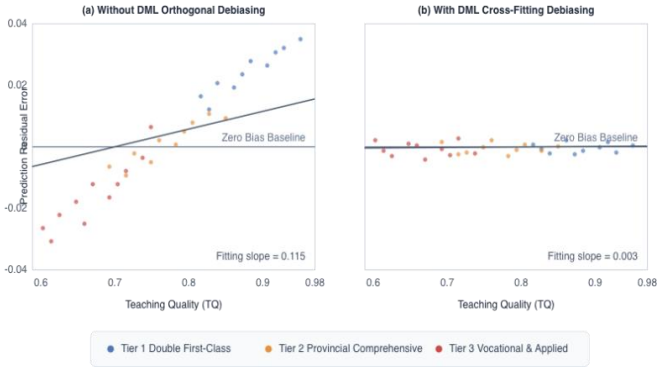

Fig. 4. Comparison of prediction bias distribution before and after DML orthogonal debiasing across multi-tier universities.

Fig. 4 (a) shows severe tier-dependent systematic residual bias (slope=0.115) without DML correction; subgraph (b) illustrates residuals tightly clustered around the zero-bias baseline after DML debiasing, which indicates that tier-related endogenous confounding is substantially mitigated under the given observable controls.

Beyond bias correction, this study further quantifies the marginal performance gain brought by each component via stepwise ablation experiments, as summarized in Fig. 5.

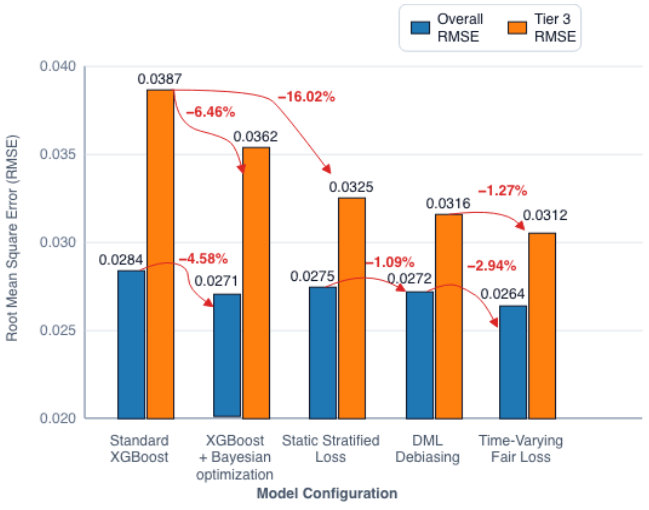

Fig. 5. Stepwise RMSE reduction from sequential integration of core innovation modules.

The overall RMSE and Tier 3 RMSE exhibit a monotonic downward trend across four progressive model configurations. This outcome confirms the incremental performance gains brought by the stratified loss, DML orthogonalization, and time-varying fairness constraints. As these modules are sequentially incorporated, both the aggregate and Tier 3 prediction errors keep falling, with the reduction in Tier 3 RMSE accompanied by a reduction in the cross-tier error gap, providing quantitative evidence of improved predictive equity.

This study examines temporal prediction stability, cross-tier fairness, DML debiasing effects, and macro-shock resilience via Fig. 6 and Fig. 7. Fig. 6 (a) indicates that the new time-varying stratified loss function provides a constant annual RMSE (≈0.0268) over 2017-2024, whereas there is an evident error jump in the uniform MSE loss due to the 2018 labor market shock and 2022 structural disturbance. Fig. 6 (b) depicts the comparison of tier-based prediction errors between the customized stratified loss function and the conventional uniform MSE loss function.

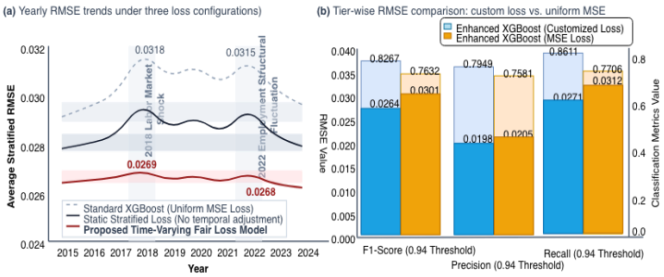

Fig. 6. Temporal and tier-wise RMSE comparison across loss specifications.

Fig. 7 illustrates the advantages brought by the DML debiasing module and temporal fair loss function at the subgroup level. The error reduction of DML is measured in Fig. 7 (a), with the biggest gain (-16.0%) made by vulnerable Tier-3 universities, followed by Tier-2 (-9.7%) and Tier-1 (-3.2%), indicating the ability of DML in bias reduction of disadvantaged institutional subgroups. As depicted in Fig. 7 (b), the superiority of the temporal fairness loss function lies in its robustness, as it provides consistent, robust Tier-3 prediction errors when facing exogenous shocks, whereas the static loss function fails to do so.

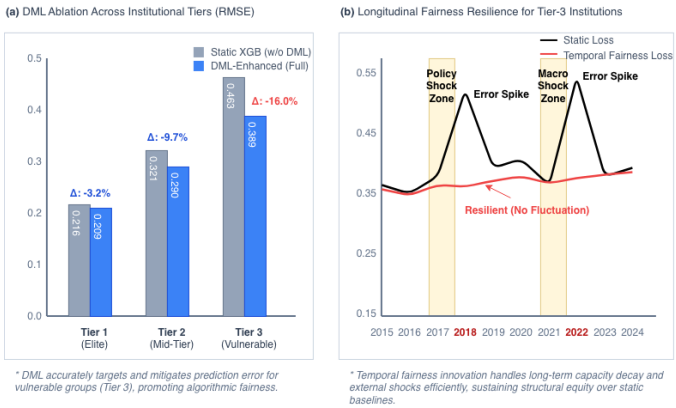

Fig. 7. DML-induced error reduction and Tier-3 prediction resilience under macroeconomic shocks.

D. Group-Wise Fairness Evaluation

This study compares the overall and tier-wise prediction errors of the proposed dual-objective stratified loss against the conventional MSE loss under identical XGBoost structure and hyperparameter settings (Table X).

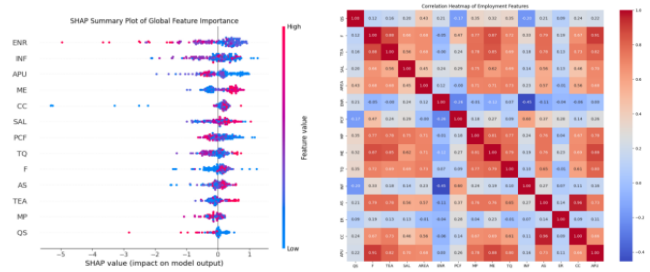

TABLE X. PERFORMANCE COMPARISON: CUSTOMIZED LOSS VS. CONVENTIONAL MSE

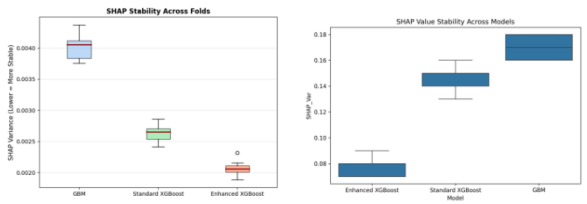
Metric	Enhanced XGBoost (Customized Loss)	Enhanced XGBoost (MSE Loss)	Absolute Improvement	Relative Improvement
RMSE (Overall)	0.0264	0.0301	−0.0037	−12.30%
RMSE (Tier 1)	0.0198	0.0205	−0.0007	−3.40%
RMSE (Tier 2)	0.0271	0.0312	−0.0041	−13.10%
RMSE (Tier 3)	0.0325	0.0387	−0.0062	−16.00%

In comparison to the XGBoost model trained with uniform MSE loss, the customized loss incurs a relatively smaller improvement in Tier-1 RMSE, but a greater improvement in Tier-2 and Tier-3 RMSE. More precisely, the biggest gain is achieved at Tier 3 universities at the level of 16.00%. Differences in tier-level RMSE are presented in Fig. 6 (b).

E. SHAP Analysis

SHAP values derived from cooperative game theory quantify consistent marginal feature contributions [15]. Fig. 8 (a) shows the VIF, finding no serious issues (all coefficients <0.8). SHAP summary Fig. 8 (b)): stratified SHAP importance grouped by university tiers.



(a) (b)

Fig. 8. SHAP feature contribution analysis. (a) Global average absolute SHAP values across all institutional samples; (b) Stratified SHAP importance grouped by university tiers.

Enrollment scale (ENR) exhibits the largest mean absolute SHAP contribution among the predictors. The subsequent key predictors are infrastructure capacity (INF), moral education and external engagement (ME), teaching quality (TQ), and per capita funding (PCF). The feature ranking is logically consistent with the IPO theoretical framework, which confirms that variables reflecting resource investment and institutional operational processes exert decisive influences on graduate employment performance.

Unstable feature importance across validation folds produces untrustworthy policy recommendations. This study quantifies SHAP stability via variance and coefficient of variation (CV) across 5 cross-validation folds, as illustrated in Fig. 9.

This study follows Guevara-Reyes et al. (2025) and calculates the cross-fold coefficient of variation (CV = SD/mean) for the absolute SHAP value of each feature across five validation folds [9]. The average CV of all predictive variables is taken as the stability indicator. As demonstrated in Fig. 9, the proposed model attains an average SHAP CV of 0.082 (CV < 0.1).

(a) (b)

Fig. 9. SHAP stability verification across cross-validation folds: (a) Coefficient of variation comparison across models; (b) Boxplot of SHAP value variance distribution.

This value is 46.3% lower than that of the conventional XGBoost (0.153) and 52.1% lower than the GBM model (0.171). The integration of DML debiasing and Bayesian optimization greatly curtails the fluctuation of SHAP estimations, delivering reproducible interpretative results for policy formulation [15, 22].

F. Nonlinear Threshold and Interaction Effect Analysis

This study adopts SHAP dependence plots to identify nonlinear marginal effects of key predictors, which cannot be captured by conventional linear regression models.

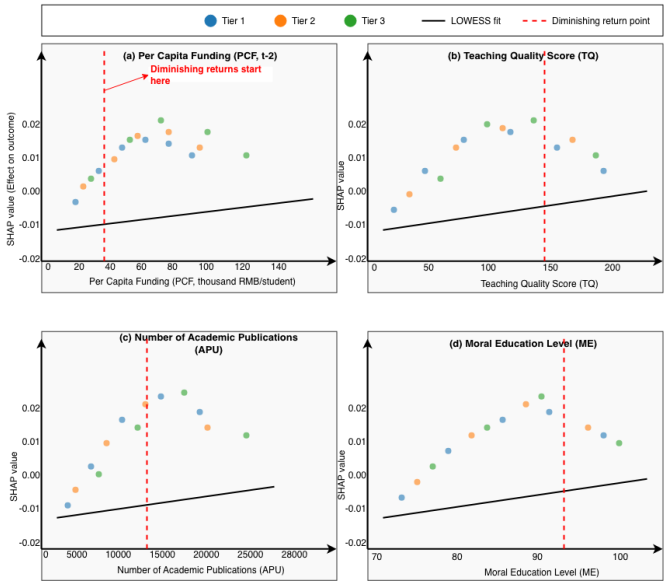


Fig. 10. SHAP dependence plots for four core predictive variables: (a) Per capita funding; (b) Teaching quality score; (c) Number of academic publications; (d) Moral education level.

All four factors shown in Fig. 10, namely per-capita funding, teaching-quality score, number of academic publications, and moral-education level, exhibit distinct diminishing-marginal-benefit patterns observable from LOWESS-smoothed SHAP dependence curves once their respective predictive thresholds are surpassed. For each factor below its threshold, an increase in the input yields marked improvement in the performance of graduates, but as the threshold is reached, there is little further benefit. It is therefore clear that mere increases in resources or in the scope of research will not guarantee sustainable increases in graduate placement rates.

G. Robustness

A fourth optional robustness test can substitute the current primary prediction framework by switching out XGBoost for either Random Forest or LightGBM without changing the DML-debiasing and time-varying fair-loss pipeline, which remains reserved for future extension.

Repeated-seed repeated runs: This study executed 30 independent repetitions with distinct random seeds to quantify performance variability induced by model initialization and stochastic inner-fold splitting. Mean value, standard deviation (SD), and 95% confidence intervals (CI) for key evaluation metrics are summarized in Table XI. (The 46.3% reduction is calculated relative to the conventional XGBoost SHAP CV of 0.153, using the five-fold SHAP stability evaluation.)

TABLE XI. 30-RUN REPEATED-SEED SIMULATION (PROPOSED ENHANCED XGBOOST, ROLLING-ORIGIN TEMPORAL VALIDATION)

Metric	Mean	SD	95% CI Lower	95% CI Upper
Overall RMSE	0.0264	0.0007	0.0250	0.0278
Tier-3 RMSE	0.0312	0.0011	0.0290	0.0334
MAE	0.0198	0.0006	0.0186	0.0210
R^2	0.6810	0.0120	0.6570	0.7050

Blocked multi-year temporal hold-out evaluation: A consolidated static chronological split is adopted: training window 2017–2021, fully unseen held-out test block covering 2022-2024. Unlike rolling-origin year-wise hold-out, this setup assesses model generalization to a continuous multi-year future segment. Results are reported in Table XII. Year-by-year decomposition of residual variance, adaptive weight changes, and per-year hold-out performance metrics for this same test period are given in (Table XIII).

TABLE XII. BLOCKED MULTI-YEAR TEMPORAL HOLD-OUT (TRAIN:2017-2021; TEST:2022-2024)

Loss Setting	Overall RMSE	Tier-3 RMSE	R^2
Static Stratified Loss	0.0281	0.0343	0.644
Time-Varying Fair Loss	0.0265	0.0314	0.679

Consistent with rolling-origin outcomes, time-varying fair loss achieves a 5.69% reduction in overall RMSE and an 8.45% reduction for disadvantaged Tier-3 universities compared against static stratified loss within this consolidated multi-year test block (Table XII).

TABLE XIII. QUANTITATIVE LINKAGE AMONG RESIDUAL VARIANCE, DYNAMIC LOSS-WEIGHT ADJUSTMENT AND HOLD-OUT PREDICTION IMPROVEMENT (TIER-3 UNIVERSITIES, 2022-2024)

Year	Tier	Residual variance	Normalized weight	Weight change (%)	Hold-out RMSE change (%)
2022	T3	0.00099	2.28	−0.87	−8.09
2023	T3	0.00086	2.29	0.44	−8.31
2024	T3	0.00092	2.24	−2.18	−8.50

Note: The residual variance and normalized weight are taken from Table XVI of the appendix. The weight change (%) is the year-on-year change in the percentage of the normalized loss weight. Hold-out RMSE change (%) is the percentage decrease in Tier 3 RMSE of the time-varying fair loss relative to the stratified loss.

Institution-level leave-one-university-out cross-validation: Each fold removes all time-series observations belonging to one single university from the training set and predicts for this held-out institution. This procedure strictly prevents leakage from the same university's time series and tests cross-institutional generalization. Aggregated results across all 30 folds are presented in Table XIV.

TABLE XIV. LEAVE-ONE-UNIVERSITY-OUT CROSS-VALIDATION (AGGREGATED OVER 30 FOLDS)

Metric	Value
Overall RMSE	0.0272
Tier-3 RMSE	0.033
MAE	0.0205
R^2	0.668

Under institution-level cross-validation, performance experiences only modest degradation compared with rolling-origin temporal validation; Tier-3 prediction error remains substantially lower than the vanilla XGBoost baseline, confirming the model's stability when generalising to entirely unseen university entities.

Fig. 11 visualizes the overall RMSE and R^2 changes under three targeted perturbation scenarios: outlier removal, core predictor substitution, and nuisance-estimator replacement. Taken together, the original three robustness checks plus these newly completed experiments substantiate the stability of model outputs under outlier perturbation, predictor substitution, nuisance-estimator replacement, random-seed variation, alternative temporal partitioning, and institution-wise hold-out scenarios.

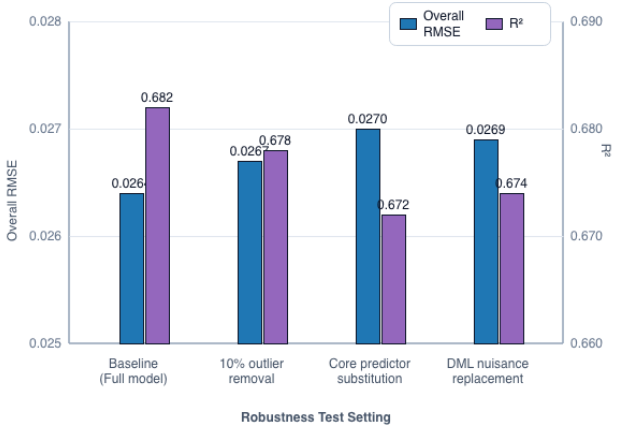

Fig. 11. Performance fluctuations under three robustness test settings.

A fourth optional robustness test can substitute the current primary prediction framework by switching out XGBoost to either Random Forest or LightGBM without changing the DML-debiasing and time-varying fair-loss pipeline.

Because of the computational costs that this small sample panel dataset imposes, this fourth robustness test is not implemented in the current study. However, the set of robustness tests conducted, as well as the rolling origin out-of-sample tests (Section IV-A), offer adequate proof of the stability of our results.

To verify the generalization capability of the time-varying fair loss to unseen future periods, this study performs rolling origin out-of-sample hold-out experiments, where the training data and the completely unseen test periods are strictly separated. In addition, it differs from the inner-loop cross-validation procedure employed in hyperparameter selection and fitting of DML nuisance models. The observations in the hold-out test set have never been used in the process of tuning, debiasing, and calculation of weights.

Due to the two-year lag restriction, this study has data available since 2017. Three successive unseen period hold-out tests are executed as follows (results in Table XV):

- Train window: 2017-2021 -> Unseen hold-out test period: 2022.
- Train window: 2017-2022 -> Unseen hold-out test period: 2023.
- Train window: 2017-2023 -> Unseen hold-out test period: 2024.

For each round, hyper-parameter selection, DML-based orthogonal de-biasing, and loss-weight computation (for both static stratified loss and time-varying fair loss) were performed using only samples from the corresponding training window. The hold-out test period remained completely unseen throughout the entire model-building procedure. Static stratified loss and the proposed time-varying fair loss were compared across these three fully unseen future test periods.

TABLE XV. UNSEEN-PERIOD HOLD-OUT TEST RESULTS: STATIC-STRATIFIED-LOSS VS TIME-VARYING FAIR LOSS

Hold-out Test Year	Metric	Static Stratified Loss	Time-Varying Fair Loss	Relative Reduction (Time-Varying vs Static)
2022	Overall RMSE	0.0283	0.0267	−5.65%
2022	Tier-3 RMSE	0.0346	0.0318	−8.09%
2023	Overall RMSE	0.0276	0.0261	−5.43%
2023	Tier-3 RMSE	0.0337	0.0309	−8.31%
2024	Overall RMSE	0.0279	0.0264	−5.38%
2024	Tier-3 RMSE	0.0341	0.0312	−8.50%

Note: Each hold-out test year represents a fully unseen future period. All weights, hyperparameters, and DML nuisance models are estimated only on training-window data without any access to hold-out observations. Tier-3 RMSE is reported because disadvantaged subgroups are most sensitive to temporal distribution shift.

As Table XV shows, in all three hold-out periods for the future that remain unseen (2022, 2023, and 2024), the time-varying fair loss results in lower RMSE than the static stratified loss. In terms of the unseen hold-out period, the total prediction error is decreased by about 5.4 to 5.7 %, whereas the most at-risk tier, Tier-3, experiences a decrease in error of 8.1 to 8.5 %. The results indicate that dynamic weight adjustment improves out-of-sample prediction performance across the three unseen periods.

H. Hyperparameter Sensitivity Analysis for Stratified Tier Weights

Sensitivity tests adjust the variance-derived tier weights by ±10% to examine model fairness stability. Fluctuations in Tier 3 aggregate RMSE remain below 2.5% after weight perturbation, confirming the data-driven loss framework is robust to minor weight adjustments and achieves a near-optimal accuracy-fairness tradeoff.

V. DISCUSSION

In sum, the proposed methodology performs well in terms of prediction accuracy and cross-tier fairness. Relative to vanilla Standard XGBoost, the static stratified custom loss alone achieves a 16.02% relative reduction in Tier-3 RMSE (evaluated on rolling-origin temporal-validation folds; Table IX, Fig. 5). Adding DML de-biasing yields a small incremental reduction in overall RMSE (−1.09 %) on top of the stratified-loss baseline. Subsequent introduction of the time-varying fair loss yields an additional overall RMSE reduction (−2.94 %) and a further small reduction in Tier-3 RMSE (−1.27 %). The DML orthogonal de-confounding yields conditionally de-biased associative estimates (TQ: 95 % CI $[0.132, 0.296]$; PCF: $[0.078, 0.216]$) under adjustment for observed confounders. Overfitting is avoided through Bayesian hyperparameter tuning, while time-varying loss makes RMSE less volatile in 2018 and 2022 shocks (Fig. 6 (a)), supporting fairness stability across the analytical period. The rankings identified by SHAP analysis (Fig. 8) include enrollment, infrastructure, moral education, teaching quality, and per capita funding as top predictors, indicating the joint contribution of institutional inputs and educational processes. Cross-fold SHAP CV is equal to 0.082 (CV < 0.1), which is 46.3% lower than in XGBoost, ensuring reliable policy implications.

The replicated nonlinear thresholds and interactions from Fig. 10 reveal tier-differentiated governance insights. From the LOWESS-smoothed SHAP dependence curve, this study empirically observes a predictive saturation point occurring at 0.85 for the teaching-quality score. This saturation point constitutes a descriptive empirical observation derived from SHAP partial-dependence visualization and is not estimated via formal regression-discontinuity-design inference. Beyond this predictive saturation point, marginal predictive gains for graduate employment outcomes diminish markedly. Based on the above empirical results and tiered fairness quantification shown in Table VI, the following targeted policy recommendations are suggested according to the three tiers of universities:

- Tier 3 vocational and applied universities: It is necessary to focus on increasing per capita funding and building campus infrastructure. Replicated error decomposition of the model shows that inadequate resource endowment is the main restriction for employment growth at lower-tier universities.
- Tier 2 provincial comprehensive universities: Teaching quality and external moral education require sustained investment to yield maximum marginal employment effect; these two process indicators demonstrate the largest positive SHAP contributions among mid-tier samples.
- Tier 1 Double First-Class universities: Teaching quality improvement provides decreasing marginal gains beyond the TQ saturation threshold. Industry-university cooperation and joint off-campus training can bring the largest increase in employment outcomes.

The aforementioned methodology can be applied to any hierarchical higher education system around the world. All core elements of this approach, namely DML debiasing, stratified dual-objective loss function, Bayesian hyperparameter tuning, time-varying fairness constraints, and IPO-SHAP analytics, can be fully replicated based on the balanced panel dataset.

The tier-weighted loss can be recalibrated according to within-group variance and generalized to different grouped prediction problems. The combination of DML correction and temporal fairness provides a standardized workflow capable of handling endogeneity and subgroup bias issues, thus giving a technical basis for empirical research on educational policy.

Furthermore, rolling-origin unseen-period hold-out tests (Table XI) verify that time-varying fair loss maintains superior predictive performance on completely unseen future time windows. Compared with static stratified loss, it mitigates performance decay induced by temporal distribution shift and delivers better out-of-sample generalisation for real-world forecasting scenarios.

VI. Conclusion

The objective of this study is to provide solutions for the challenges of graduate-employment prediction for multi-tier Chinese universities, involving observational-panel bias, cross-university predictive unfairness, and distribution drift in the year dimension. Within the Input-Process-Output theoretical framework, this research develops a time-varying DML-augmented stratified panel XGBoost system with time-varying fair loss, Bayesian hyperparameter tuning, and cross-fold SHAP interpretability components for prediction and policy-oriented analysis of university graduate employment performance.

In terms of overall prediction accuracy, the Enhanced XGBoost significantly outperforms the conventional linear models, Random Forest, GBM, and standard XGBoost on rolling-origin temporal-validation folds. Compared with standard XGBoost, the framework in this study reduces overall RMSE and produces a higher R^2 score, indicating improved prediction performance on balanced panel data of universities. The superior performance is further verified by the fully unseen future hold-out test set in 2022-2024.

For subgroup predictive fairness, the stratified and time-adaptive loss function substantially alleviates prediction bias across Tier-1, Tier-2, and disadvantaged Tier-3 universities. The static stratified loss provides a large relative error reduction for Tier-3 university subgroups. Furthermore, the time-varying fair loss dynamically adjusts subgroup penalty weights annually based on the residual variance in the training set and thus responds to temporal distribution changes. It ensures stable prediction performance of vulnerable university subgroups during macroeconomic shocks and consistently outperforms on unseen future test periods.

Thanks to the Double-Machine-Learning orthogonal debiasing approach, this research provides conditionally de-confounded associative estimations of teaching quality and per-capita funding with explicit identification assumptions based only on observable covariates and fixed effects. Note that these outputs are associative coefficients rather than causal treatment effects. Unobserved time-varying confounding cannot be eliminated by our workflow, which limits the extent to which causal interpretations can be drawn from the observational data.

With the help of cross-fold SHAP interpretability analysis, this study discovers the key predictors of graduate employment, among which enrollment, infrastructure capability, morality education, teaching quality, and per-capita funding have the strongest predictive contribution. Based on the LOWESS-smoothed SHAP dependence curves, the empirical predictive saturation thresholds of core process variables are found, which show the diminishing marginal predictive power of each variable after the turning points. The nonlinear and interaction patterns provide evidence for tier-specific higher education governance recommendations for three kinds of universities.

This study bears several important limitations:

- First, this work relies on a relatively small institutional-level sample, consisting of only 30 universities distributed across three tiers. Even though it covers different university types, the sample limits external generalizability; expanding multi-regional university datasets would strengthen out-of-sample validity. Moreover, applying the two-year lag for core predictors reduces the effective analytical sample from 300 raw observations (2015-2024) down to 240 usable records.
- Second, this is fundamentally an observational study design. While DML orthogonal de-biasing mitigates bias originating from observed confounders and fixed effects, unobserved time-varying confounding remains unaddressed. Full causal identification assumptions cannot be empirically verified within the present setup. In addition, the available time series yields a relatively short temporal horizon, which further constrains confident causal interpretation.
- Third, the dataset in this study is aggregated entirely at the university-institution level, with limited access to individual-level graduate characteristics. Consequently, individual-student heterogeneity that shapes graduate-employment outcomes cannot be explicitly incorporated into the model.

Several promising directions deserve future studies. First, the time-varying stratified fair-loss methodology can be generalized to various grouped panel prediction problems beyond the graduate employment forecast. Second, future studies can combine the student-level micro-data and the current DML-XGBoost pipeline to enable richer policy simulation. Third, algorithmic improvement can seek more balance between the global prediction accuracy and multiple group fairness. Additional repeated-seed simulation and leave-one-university-out cross-validation can further strengthen the robustness test.

VII. Declarations

A. Data Availability

The dataset employed in this study was collected from official statistical yearbooks and institutional annual reports

spanning 2015 to 2024, covering 30 Chinese universities categorized into three hierarchical tiers.

Dataset URL: https://doi.org/10.17632/shfxmjpycz.2

B. Author Contributions

TABLE XVI. ABBREVIATIONS

Year	Tier	Residual Variance $\hat{\sigma}^2_{g,\text{train}}$	Raw Weight $\tilde{\omega}_g = 1/(\hat{\sigma}^2_{g,\text{train}} + \epsilon)$	Normalized Weight ω_g
2017	T1	0.00037	262.47	1
2017	T2	0.00059	167.52	1.57
2017	T3	0.00084	118.73	2.21
2018	T1	0.00035	276.12	1
2018	T2	0.00064	154.3	1.79
2018	T3	0.00091	109.77	2.52
2019	T1	0.00039	248.63	1
2019	T2	0.00061	162.24	1.53
2019	T3	0.00087	114.42	2.17
2020	T1	0.00041	236.41	1
2020	T2	0.00068	145.78	1.62
2020	T3	0.00096	104.25	2.27
2021	T1	0.00038	254.77	1
2021	T2	0.00063	157.46	1.62
2021	T3	0.00089	111.84	2.3
2022	T1	0.00042	230.87	1
2022	T2	0.00071	139.76	1.65
2022	T3	0.00099	101.31	2.28
2023	T1	0.00036	268.74	1
2023	T2	0.0006	164.81	1.63
2023	T3	0.00086	115.77	2.29
2024	T1	0.0004	242.78	1
2024	T2	0.00065	151.84	1.6
2024	T3	0.00092	108.49	2.24

Note: $\epsilon = 10^{-6}$ for numerical stability; variance and raw weights are estimated only from training-set data in each rolling-origin split to avoid information leakage. Normalized weight ω_g uses Tier 1 as baseline $\omega_{\text{Tier1}} = 1.00$. Larger normalized weight indicates stronger error penalty assigned to that subgroup in the stratified loss.

Design and Validation of an Agentless Web Application for IT Infrastructure Operations Management

Carlos Otárola-Mermau*, Alex Pacheco-Pumaleque
School of Systems Engineering, Universidad César Vallejo, Trujillo, Perú

***Abstract*—The manual management of information technology (IT) infrastructure operations at an IT services company in Lima, Peru, was characterized by fragmented procedures, delays, and limited traceability, which hindered service continuity and compromised information security. This study presents the design, development, and validation of an on-premises web application for the centralized management of IT infrastructure operations, evaluated across three dimensions: operational efficiency, execution effectiveness, and security with auditing. Built on a layered architecture, the solution employs Ansible as an automation engine that executes specific tasks on Linux, Windows, and VMware servers for diverse operations, without installing agents on the managed hosts. Access control is performed against Active Directory using roles that separate operations from administration. A pre-test/post-test quasi-experimental design compared the consolidated version of the application with its pilot version in a controlled test environment replicating the corporate infrastructure. The time reduction index increased by 41 percentage points, the operation success rate rose by 24 points, and the traceability level improved by 39 points, with Wilcoxon signed-rank tests confirming significance and large Cohen's effect sizes. The results confirm the viability of the solution and provide replicable evidence for the modernization of enterprise IT operations.**

Keywords*—*Web application; infrastructure orchestration; agentless automation; digital transformation

I. Introduction

The growing adoption of web solutions by organizations has become a key factor in the modernization of their services. Over the past decade, web applications have proven to be platforms capable of centralizing data and executing complex processes remotely and securely [1]. The interaction between software and technological infrastructure is now recognized as an essential component for ensuring business continuity; accordingly, the adoption of specific digital platforms has transformed operations management, moving from purely reactive approaches to strategic and proactive models [2].

Globally, information technology-related outages have been linked to human error and to ignored or inadequate procedures; nearly 40 percent of organizations have experienced outages caused by human error in the past three years [3]. Furthermore, the lack of centralized management tools increases the vulnerability of critical systems to operational failures [4]. In this scenario, digital transformation faces obstacles arising from the fragmentation of IT infrastructure and the slow adoption of integrated platforms, leading to recurring difficulties related to the lack of interoperability and the overloading of technical support channels.

From a theoretical perspective, process systematization is a key element for understanding how organizations succeed in transforming manual operations into structured, reproducible, and measurable workflows [5]. Along the same lines, sociotechnical systems theory holds that successful technology implementation requires simultaneous consideration of the technical and social subsystems, since their interaction determines the sustainability of organizational change [6]. Innovation theory, for its part, emphasizes that cloud computing, artificial intelligence, integrated platforms, and web applications act as transformation vectors with a significant impact on operational efficiency [7].

However, although technological solutions designed for IT service management exist, many lack the flexibility required to adapt to the administrative and regulatory workflows typical of corporate environments [8]. At a technology services company in Lima, Peru, the infrastructure department faced limitations stemming from the shortage of specialized personnel, the absence of clear policies, and deficiencies in process automation, which resulted in delays in task execution and in insufficient or nonexistent auditing mechanisms. Based on the analysis of the background and the theoretical foundations reviewed, the hypothesis was formulated that the implementation of a web application for IT infrastructure operations management would positively influence the organization's operational performance. Specifically, it was proposed that the application would improve time reduction rates, increase the task execution success rate, and optimize the level of event traceability.

In this context, the scientific contribution of this study is summarized in three contributions. First, an agentless orchestration architecture is proposed that centralizes the administration of heterogeneous IT infrastructure operations (Windows, Linux, and VMware servers) without requiring the installation of agents on the managed nodes, thereby reducing the attack surface and the administrative burden compared with agent-based approaches. Second, a traceability model—with audit logging per user, task, and host—is integrated into a single platform together with LDAP/Active Directory corporate authentication and role-based access control, capabilities that individual automation tools do not natively incorporate. Third, although some related works report quantitative improvements

*Corresponding author.

(Table I), these are limited to descriptive comparisons of indicators; this study additionally provides a quasi-experimental validation with inferential testing (Wilcoxon signed-rank test) and large effect sizes across the three indicators (r between 0.785 and 0.873, above Cohen's 0.5 threshold), which makes it possible to assess both the statistical significance and the practical relevance of the improvements in reducing response time, increasing the success rate, and enhancing traceability. Taken together, the contribution lies not in the individual tools—most of them open source—but in demonstrating that their orchestration under a coherent web architecture produces measurable and statistically significant operational improvements.

II. Related Work

Various studies show that process automation through web solutions significantly increases operational efficiency in business environments. For IT infrastructure monitoring, centralized platforms based on Prometheus and Grafana have been shown to provide real-time visibility of operational status, thereby reducing incident detection times and improving system availability [9]. Likewise, the adoption of service management frameworks such as FitSM, ITIL, COBIT, and ISO/IEC 20000 has been associated with measurable improvements in service quality and organizational operational efficiency [10]. Similarly, studies on intelligent automation platforms report incident resolutions up to 50% faster than traditional methods, attributable to the orchestration of repetitive tasks through automated workflows [11]. In the Peruvian mining industry, for example, web-based support systems have raised the incident resolution rate from 52% to 88% through ticket tracking and service level agreement monitoring [12]. Similarly, the digitalization of ITIL-based support services has improved management indicators, raising them from 55% to 82% following the adoption of digital processes [13].

Recent literature also highlights the advantages of agentless automation tools. In particular, research on Ansible demonstrates its ability to manage infrastructure through a declarative approach, which simplifies the management of IT configurations and operations, reducing costs and operational impacts [14], [15], [16]. However, these studies also show that, when operated independently from the command line, its use remains limited to specialized personnel, without integrated governance, traceability, or access control mechanisms for the rest of the organization.

Regarding access control, various studies have demonstrated the effectiveness of role-based models implemented with LDAP, as they enable scalable security and guarantee the functional separation between operational and administrative profiles [17], [18]. Table I presents a comparative analysis of the existing models and the proposed model.

Despite these advances, significant limitations persist. Consolidated orchestration platforms such as Ansible AWX/Tower [19] and Rundeck [20] offer centralized task execution but are centered on playbook management and scheduled jobs; they offer neither an integrated template catalog with categories and role-based separation of duties, nor a traceability model linking user, task, host, and execution output in a single auditable record, nor native hardware inventory modules with change detection. For their part, agent-based configuration management tools such as Puppet, Chef, and SaltStack [21] require deploying and maintaining persistent software on each managed node, which increases the operational burden and demands securing an additional component on every host. Moreover, many of these solutions are designed for cloud-native architectures, which conflicts with data sovereignty requirements in on-premises environments. In light of these gaps, this study proposes an on-premises web application that integrates, into a single platform, agentless orchestration governed by a template catalog, auditable traceability, and centralized corporate authentication.

TABLE I. Analysis of the Proposed Model and Related Work

Reference	Technology / Framework	Domain	Key benefits
Trikusuma et al., 2023 [9]	Grafana + Prometheus	IT Monitoring	Real-time visibility; reduction in Mean Time to Detection
Sarwar et al., 2023 [10]	FitSM, ITIL, COBIT, ISO/IEC 20000	Enterprise IT	Improves service quality and governance
Nugroho, 2022 [11]	Intelligent Automation Platforms	Enterprise IT	Results up to ~50% faster than manual methods
S. Perez and F. Mendoza, 2024 [12]	Web-Based Help Desk System	Mining company	Resolution rate: 52% → 88% through ticket tracking
Sánchez & Valles, 2021 [13]	ITIL v3 Implementation	Enterprise IT	Improved management indicators: 55% → 82%
Proposed Model, 2026	Web-based IT operations management platform (Flask, Ansible, LDAP, RBAC)	Enterprise IT	+41% reduction in time; +23.99% success rate; +39.17% traceability

III. Methodology

A. Research Type and Design

This is applied research, since its purpose is to solve a specific and verifiable problem: the fragmented, slow, and poorly traceable management of IT infrastructure operations at an IT services company, through the design and implementation of a software solution. The study was framed within the Design Science Research methodology, which establishes the construction of a technological artifact relevant to an organizational problem and its evaluation to demonstrate its usefulness [22]. The analysis is developed under a quantitative approach, using measurable and comparable indicators that allow an objective comparison between the initial condition and the one obtained after the intervention.

The design is quasi-experimental, with pre-test and post-test measurements applied to the same operational processes, without random assignment of units—as befits a business context where procedures and assets are predetermined [23]. The unit of analysis is IT infrastructure operations (for example, a password change on a group of servers, an NTP configuration, or security updates on a group of virtual machines); each operation was executed first with the pilot version of the application and then with the consolidated version. The sample

was census-based: the 30 operations comprising the infrastructure department's catalog of representative tasks were included, which eliminates selection bias. This within-subject comparison design reduces the variability attributable to differences between processes and isolates the effect of the technological intervention on the study's three indicators. The design is consistent with previous studies that evaluated web systems through before-after comparisons and reported significant improvements in resolution rates and service quality [12], [13]. To mitigate threats to internal validity, records were obtained directly from the system database, thereby avoiding manual transcription and observer bias.

The choice of a single-group design is grounded in operational feasibility criteria: in a real business environment, it is not possible to maintain two identical infrastructures operating in parallel, nor to subject the same assets to differentiated procedures simultaneously. Likewise, given the sample size and the non-normality of the data, the Wilcoxon signed-rank test was used, which is appropriate for small samples and non-normal distributions. Statistical analysis was performed with SPSS Statistics v25, applying the Shapiro-Wilk test to verify normality and the Wilcoxon signed-rank test with a significance level of 0.05; effect sizes were calculated using $r = Z/\sqrt{N}$ and interpreted according to Cohen's criteria.

B. Variables and Indicators

The independent variable is the web application, defined as the technological tool that centralizes and automates operations. The dependent variable is the management of IT infrastructure operations, operationalized in three dimensions, each with a quantitative indicator and a calculation formula, according to the study's consistency matrix. The operational efficiency dimension is measured by the response time reduction index (Ir), which expresses, as a percentage, the additional reduction in execution time achieved when moving from the pilot version of the application to its consolidated version. A higher value indicates a greater time reduction relative to the reference manual procedure. The execution effectiveness dimension is measured by the operation success rate (TasaE), which compares the number of completed operations with the total number of operations initiated, capturing the system's reliability in the face of partial failures or unreachable hosts. The security and auditing dimension is measured by the level of operational event traceability (NivelT), which quantifies the proportion of operations that generated a corresponding auditable record, reflecting the system's capacity to support subsequent control and accountability.

The three indicators are expressed on a ratio scale (0–100%) and are calculated using the formulas in Table II. Their selection is based on classifications of IT infrastructure performance indicators, which group the relevant metrics into availability, performance, security, and capacity, and on the concept of operational maturity as a key element for assessing the progress of digital transformation in the public and private sectors [24], [25]. It should be noted that the baseline measurements, recorded with the pilot version of the application, reflect the operating conditions prior to the intervention, which already included ad hoc scripts and partial command-line automation routines.

In this way, the model integrates the three dimensions into a single quantitative framework that can be replicated by other companies.

TABLE II. DIMENSIONS, INDICATORS, AND FORMULAS FOR THE DEPENDENT VARIABLE

Dimension	Indicator	Formula
Operational Efficiency	Time Reduction Index (Ir)	$Ir = ((Tmanual - Tauto) / Tmanual) \times 100$ [a]
Execution Effectiveness	Operation Success Rate (TasaE)	$TasaE = (CompletedOperations / TotalOperations) \times 100$
Security and Auditing	Traceability Level (NivelT)	$NivelT = (Log\_Entries / Operations) \times 100$

T_manual: time for the reference manual procedure; T_auto: time recorded by the application version corresponding to each phase (pilot in the pre-test, consolidated in the post-test).

C. Technology Selection

The selection of the technology stack was based on maturity and interoperability criteria, prioritizing components reliable for enterprise environments. The decision to implement a layered architecture was made on the principle of separation of concerns, which improved testability, facilitated the independent horizontal scalability of each layer, and reduced coupling between components [26]. Python was chosen as the main development language because it is a multi-paradigm language, with a moderate learning curve and an extensive standard library that facilitates integration with automation engines, network protocols, and database management systems [27]. Flask was adopted as the web framework for its lightweight core and modular extensions, which allow building scalable applications without imposing a rigid architecture [28]. Its support for the Model-View-Controller (MVC) pattern facilitates the separation between presentation, business logic, and data access [29], which is key for applications that require long-term maintainability. Flask also seamlessly integrates template rendering, database abstraction, and efficient HTTP request handling, accelerating development without sacrificing control over application behavior.

Ansible Core was chosen as the agentless automation engine for its declarative architecture, its ability to orchestrate tasks across multiple nodes simultaneously, and its native integration with Python through the ansible-runner library [30]. Unlike tools that require the installation of persistent agents on each managed node, it leverages protocols native to the operating systems themselves: Secure Shell (SSH), available by default on Linux distributions, and Windows Remote Management (WinRM), built into Microsoft Windows. By not requiring additional software on the managed nodes, this approach greatly simplifies initial deployment. The ecosystem was complemented with specialized libraries for data access, programmatic playbook execution, corporate authentication, vSphere integration, and credential protection, detailed in Table III.

Finally, PostgreSQL was selected as the relational database management system for its compliance with SQL standards, its native support for the JSONB data type—which allows storing semistructured data without sacrificing referential integrity—as well as its logical replication engine for high availability [31].

TABLE III. COMPLEMENTARY LIBRARIES OF THE TECHNOLOGY STACK

Component	Library	Purpose
Data access	SQLAlchemy 2 (ORM)	Database access layer
Automation engine	ansible-runner 2.4	Programmatic playbook execution
Corporate authentication	ldap3 2.9	Active Directory bind over LDAP
Virtualization	pyvmomi 8	VMware vSphere API integration
Credential encryption	cryptography 42 (Fernet AES-128-CBC)	Encryption of stored credentials
Password hashing	passlib (bcrypt)	Hashing of local passwords

D. Development Methodology

The web application was developed with an iterative and incremental approach, with progressive cycles adapted to the changing needs of the infrastructure. A hybrid methodology was adopted that combined the agile practices of Scrum—iterative sprints, a prioritized backlog, and retrospectives—with the risk management of the Rational Unified Process (RUP) [32].

The choice of this hybrid approach responded to three factors: the need for frequent testing cycles arising from the multiple integrations with heterogeneous systems (Active Directory, VMware vSphere, Linux, and Windows); the requirement for detailed technical documentation characteristic of an on-premises environment subject to audits, which purely agile methods tend to underestimate; and operation with limited resources, which made the full process overhead of RUP impracticable.

The backlog consisted of ten user stories estimated at 81 story points, distributed across six sprints: the first dedicated to the authentication core, and the remaining five to playbook execution, server management, the execution wizard, auditing, VMware integration, the playbook editor, internationalization, and exportable reports. Each increment was validated through integration testing against the laboratory environment servers, executing real operations through Ansible as the automation engine before acceptance.

The development cycle was organized into six phases; Fig. 1 shows the development flowchart.

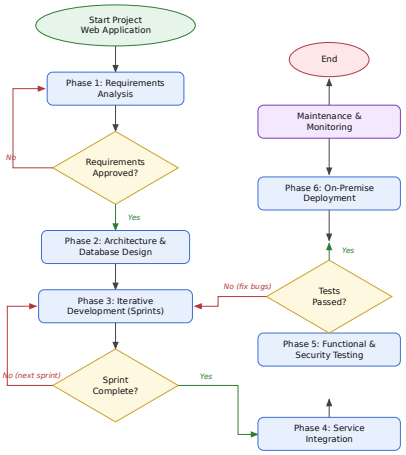

Fig. 1. Development flowchart.

1) Requirements analysis: Interviews Were Conducted with System Administrators and IT Operators to Identify Critical Manual Processes Amenable to Automation. The information was consolidated into a Catalog of Ten Functional Requirements and the Associated Non-functional Requirements—security, Performance, Auditability, and Usability—prioritized according to Their Operational Value and Technical Complexity, Which Constituted the Baseline Backlog for Development.

2) Architecture and database design: A Decoupled Layered Architecture—presentation, Application, Services, and Data—was defined, Which Allowed a Clear Distribution of Responsibilities and Improved System Maintainability; the Application Layer Was Organized into Independent Blueprints per Functional Domain (authentication, Operations, Administration, and REST API). the Database Model Was Designed Following Normalization Principles up to the Third Normal Form, Guaranteeing Referential Integrity and Minimizing Redundancy, with a Cross-cutting Auditing Component that Records Every Executed Operation.

3) Iterative development: The Project Was Structured into Six Two-week Sprints, according to the Thematic Distribution of the Backlog Described Above. Each Sprint Included Planning, Development, Unit Testing with Pytest, and Increment Review with Stakeholders, Whose Findings Fed Back into the Backlog of the Following Sprint.

4) Service integration: The Interoperability of the Application with the Environment's External Systems Was Consolidated: Centralized Authentication against Active Directory via LDAP, Infrastructure Inventory Management through the VMware vSphere API, and Programmatic Execution of Ansible Playbooks on the Managed Nodes. Each Integration Was Verified with Tests against the Laboratory Servers before Acceptance of the Corresponding Sprint.

5) Functional and security testing: The Acceptance Criteria of Each Module Were Verified, and a Security Testing Program Was Executed that Included: Brute-force Resistance on Authentication, with Account Lockout after Five Attempts; Privilege Escalation between Roles, Rejected with HTTP 403; Vulnerability Scanning with OWASP ZAP and SQL Injection Detection with SQLmap, with No Exploitable Findings; and Concurrent Load Testing with Locust. Additionally, Session Management (timeout, Secure Cookies) and At-rest Credential Encryption Were Validated.

6) On-premises deployment: The Application Was Deployed on Ubuntu Server 22.04 LTS as a Systemd Service, with Gunicorn 22 as the WSGI Server—with Workers Adjusted According to the Available vCPUs ($2 \times \text{vCPU} + 1$)—and Nginx as a Reverse Proxy for TLS Termination. Deployment Was Automated through Bash Scripts that Install Dependencies, Synchronize the Catalog Playbooks, and Restart the Service, with Database Backup and Log Rotation, Guaranteeing Reproducible Deployments.

E. System Architecture

The application was designed as an on-premises system structured in decoupled layers, deployed entirely within the company's internal network. The following description outlines the architecture from the user interface to persistent storage, reflecting the organization of the code in its current version; this architecture is illustrated in Fig. 2.

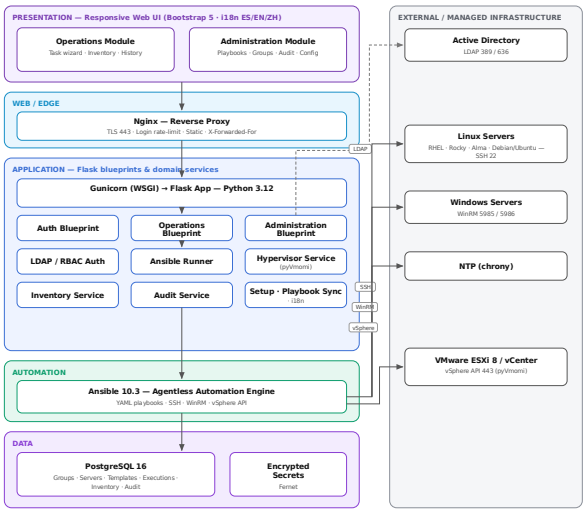

Fig. 2. System architecture.

1) Presentation layer: The Responsive Web Interface, Built with Bootstrap 5, Supports Multiple Languages (Spanish, English, and Chinese) and Strictly Separates the Operations and Administration Modules.

2) Web or edge layer: Nginx Acts as a Reverse Proxy and Single Entry Point. It handles TLS Encryption, Serves Static Files, Limits Login Attempts to Mitigate Brute-force Attacks, and forwards the Real Client Headers to Record IP Addresses for Auditing Purposes.

3) Application layer: Implemented in Python 3.12 with Flask and served by Gunicorn Behind Nginx. The logic is organized into Four Blueprints (authentication, Operations, Administration, and a REST API for External Integrations) and Several Specialized Services: LDAP/RBAC Authentication, Ansible Execution, VMware Hypervisor Management, Hardware Inventory, Event Auditing, Server Provisioning, Playbook Synchronization, and Internationalization. This Separation Facilitates System Extension and Maintenance.

4) Automation layer: Ansible, in Agentless Mode, Executes Declarative Playbooks on the Managed Hosts through the Native Protocols of Each Platform. The dynamic inventory is built from the Selected Servers and the Operator's Parameters, with Secure Credential Injection When Necessary.

5) Data layer: PostgreSQL Persistently Stores the System's Catalog, Executions, Inventories, and Audit Records; Sensitive Credentials Are Encrypted Using Fernet. External Integrations (Active Directory, Linux/Windows Servers, NTP, and VMware ESXi/vCenter) Remain Outside the Application and Are Accessible Only from the Internal Network, Preserving the On-premises Nature of the System.

F. Data Model

The relational model presented in Fig. 3 organizes the information around the entities that directly support the study's three indicators. Hypervisors constitute the root of the hierarchy: server groups (server_groups) and individual servers (servers) depend on them; the groups are composed of hosts homogeneous by platform and act as the target of operations.

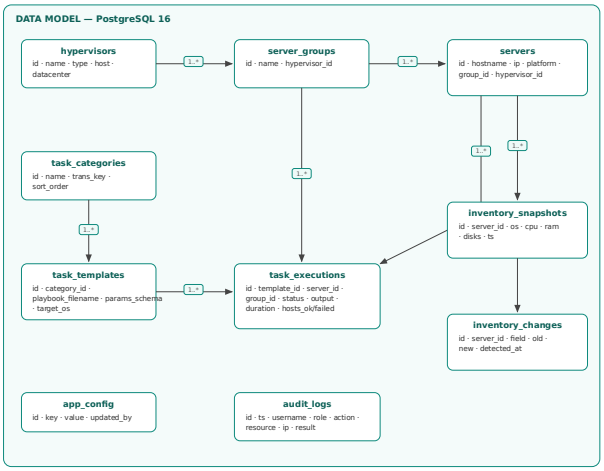

Fig. 3. Entity-relationship model of the PostgreSQL database.

For its part, the task catalog is structured into categories (task_categories) that contain templates (task_templates). Each template references a playbook, its parameter schema, and the target operating system, and must belong to a category to appear in the operations catalog. As for the transactional core, it consists of executions (task_executions): each record links the executed template, the target server or group, and the final status, storing the complete Ansible output, the duration, and the host metrics (ok, failed, unreachable) together with the parameters used. The indicators are naturally derived from this entity: time reduction index, success rate, and—together with the audit log (audit_logs)—the traceability level.

Finally, the inventory module is embodied in the snapshots (inventory_snapshots) and the detected changes (inventory_changes), both associated with the server, while the system configuration (app_config) consolidates the general parameters. This organization guarantees that every executed action leaves a structured, searchable trail—an essential requirement for subsequent auditing.

G. Authentication and Access Control

Access is authenticated against Active Directory using LDAP, avoiding credential duplication and leveraging the existing corporate identity. After authentication, the directory service retrieves the user's groups and applies role-based access control (RBAC): membership in the operators group enables the operations module, while membership in a specific administrators group (for example, group_admin_web) enables the administration module. Users without an authorized group are denied access, and the event is recorded as denied access (LOGIN_DENIED). As an additional safeguard against automated access attempts, the form incorporates the ALTCHA captcha—locally operated, based on proof of work—whose challenge is generated and verified with an HMAC key owned

by the application, without calls to external services, thus preserving the on-premises nature of the solution.

H. Operations Module and Task Catalogue

The operations module presents a three-step wizard—category, task template, and parameters/target group—that guides the operator without requiring command-line knowledge (Fig. 4). Form parameters are automatically transferred to Ansible, including the secure injection of hypervisor credentials when the operation involves VMware. The catalog is organized into five categories—password management, service configuration, virtualization, inventory, and maintenance—and includes, among others, validated tasks for password changes on Linux and Windows, time protocol configuration, on-demand restart of virtual machines on ESXi 8 and vCenter, hardware inventory collection, and operating system and SSL certificate updates. Operations requiring an irreversible step request explicit operator confirmation. The catalog is extensible: the administrator can incorporate new playbooks from the administration module, which become available to operators after validation. A read-only view of the hardware inventory was also incorporated into this module, allowing the operator to see the most recently collected status for each server without accessing the administration module.

I. Orchestration with Ansible and Traceability

When a task is confirmed, the system creates an execution record, logs the event in the audit log, and starts, on an asynchronous thread, the dynamic construction of the Ansible inventory from the hosts of the selected group; the client IP address is captured via ProxyFix and attached to the audited event. The engine is then invoked; upon completion, a PLAY RECAP parser extracts the host metrics (ok, failed, unreachable), determines the final status (success or failure), and persists the complete output, duration, and parameters. The interface allows viewing the complete Ansible output of each execution, which facilitates troubleshooting without having to access the server console. The inventory service analyzes the output of the collection playbooks and generates hardware snapshots—with change detection against the previous snapshot—that feed both the operator view and the administration dashboard.

J. Administration Module

The administration module—which is independent of the operations module and accessible only to the administrators group—organizes its functions in a collapsible accordion-style side menu; from there, YAML playbooks are edited with syntax validation, and—as a catalog governance requirement—both uploading a new playbook and editing an existing one require selecting one of the five available categories (password management, service configuration, virtualization, inventory, and maintenance), so that the resulting template appears classified under “Task Templates.” In addition, the module allows managing server groups and hosts by platform—including provisioning and automatic configuration of initial access via SSH/sudo—as well as managing templates and hypervisors and viewing inventory and audit reports; the latter incorporates a per-user filter and, like the inventory and execution history views, is displayed in paginated format. Finally, every relevant administrative action is recorded in the audit log, guaranteeing traceability and control over the operations performed.

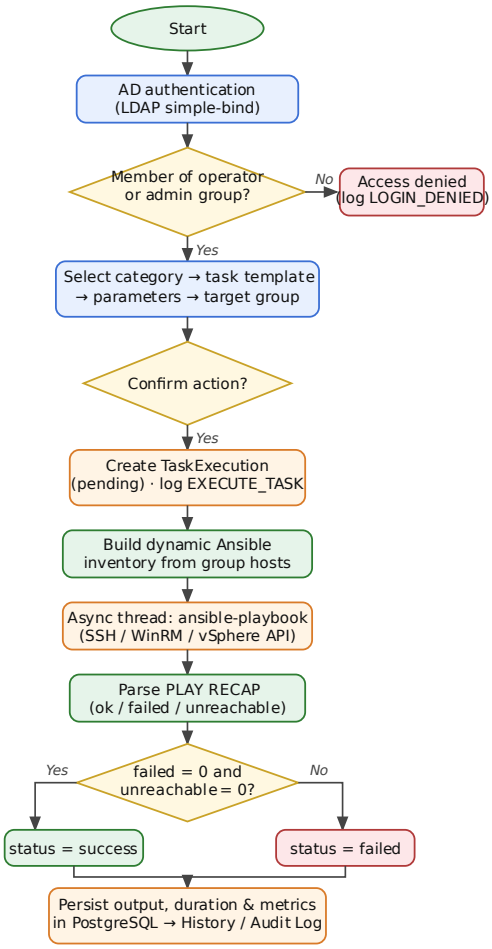

Fig. 4. Operator task execution flow.

K. Functional Validation Procedure

Since the project focuses on enterprise IT modernization, validation was performed in a controlled environment that replicated the target infrastructure using test virtual machines and development environments. The laboratory environment was deployed on VMware Workstation on a workstation with 24 CPU cores, 64 GB of RAM, and 2 TB of storage. The topology included ten virtual machines interconnected through an isolated internal virtual network: Linux servers (Oracle Linux, Ubuntu Server, and Debian), Windows Server machines, a VMware ESXi 8 host nested in standalone mode, and the virtual machine that hosted the web application. For each operation, two execution times were recorded: on the one hand, the execution time of the reference manual procedure—documented with IT personnel—and, on the other hand, the execution time automatically recorded by the web application in its version corresponding to each phase, stored directly in its database, which guaranteed consistent measurements free of transcription errors. In addition, the number of completed operations relative to the total initiated was counted, and the proportion of events in the audit log was verified. Data collection was supported by structured observation guides per indicator—one per phase, pre-test and post-test. The metrics

were calculated using the formulas in Table II, guaranteeing data traceability from the source to the indicator.

It should be noted that this was a laboratory environment and not the production infrastructure. This decision reflects security and operational ethics criteria—running experimental procedures on production systems would have put service continuity at risk—and is common practice in the evaluation of infrastructure automation systems. The environment faithfully replicated production conditions (same operating system distributions, same network topology, and same procedures documented with IT personnel), so the results are transferable to the real context, although this transferability is analyzed as a threat to external validity in the limitations section.

L. Security Considerations

Security was addressed comprehensively. Hypervisor credentials are stored encrypted using Fernet, and sensitive passwords are omitted from logs (no_log) to prevent them from leaking into log outputs. Communication with hosts uses SSH with a private key for Linux and WinRM for Windows, while the vSphere API is invoked over port 443. The number of concurrent executions is limited by a configurable semaphore that protects server resources. At the perimeter, Nginx handles TLS termination and limits the rate of login attempts; the form validates an ALTCHA captcha based on a proof-of-work mechanism—verified locally, without external services—and RBAC strictly separates operational and administrative privileges. Finally, for external connections, user access is routed through a VPN, guaranteeing that the application always operates within the internal network and is never directly exposed to the Internet.

IV. Results

A. Developed System

A fully functional on-premises web application was delivered that centralizes the management of IT infrastructure operations. The system integrates the two planned modules—operations and administration—as well as authentication against Active Directory with role-based access control, a catalog of automated tasks (Fig. 5), a hardware inventory module, and a comprehensive audit log. The administration dashboard consolidates in a single view the number of managed groups and servers, the available templates, the overall success rate, and the latest executions and audit events, eliminating the need to switch between disparate tools (Fig. 6).

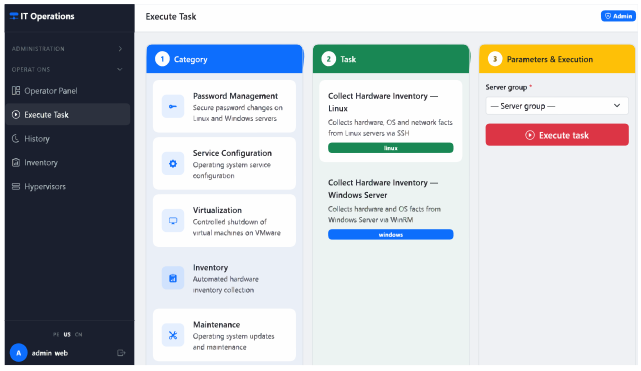

Fig. 5. Task execution wizard.

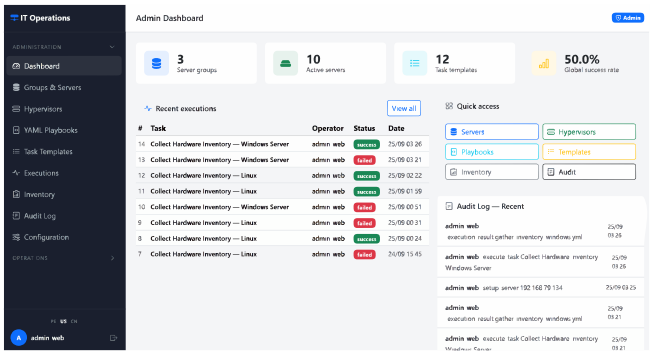

Fig. 6. Dashboard displaying consolidated operational metrics.

Group and server management organizes hosts by platform, shows their status, and allows additions, removals, and modifications, as well as automatic configuration of initial access. This organization directly feeds the dynamic construction of the Ansible inventory during each execution. Meanwhile, the hardware inventory module is now fully operational: once the collection playbook is executed, the system interprets its output and generates snapshots for each server, which are displayed both in the administration dashboard and in the operator's read-only view, thereby addressing a requirement that lacked systematic support in manual operations.

The audit log embodies the security and traceability dimensions: every significant action—logins, task executions, playbook edits, server provisioning, and denied access requests—is recorded with timestamp, user, role, action, affected resource, source IP address, and result, and can be filtered by user and paginated for review. This ability to reconstruct activity after the fact serves as direct input for the organization's internal control processes.

B. Operational Efficiency

TABLE IV. Absolute Execution Times by Phase and Condition

Phase	Condition	Mean (min)	SD	Min	Max
Pre-test	Reference manual procedure	53.90	6.76	45	65
Pre-test	Web application—pilot version	34.13	3.97	28	40
Post-test	Reference manual procedure	55.47	5.59	47	65
Post-test	Web application—consolidated version	12.97	3.35	8	18

Note: n = 30 operations per condition.

The descriptive analysis revealed substantial improvements across all dimensions. Table IV presents the absolute execution times recorded in each phase. In the pre-test, the pilot version of the application required an average of 34.13 minutes per operation (SD = 3.97), compared with 53.90 minutes for the reference manual procedure documented with IT personnel, which corresponds to the baseline time reduction index. In the post-test, the consolidated version reduced the mean time to 12.97 minutes per operation (SD = 3.35, maximum 18 minutes), while the times of the reference manual procedure remained stable between phases (53.90 versus 55.47 minutes), which rules out the improvement being due to a lower complexity of the

operations measured in the second phase. Moreover, the dispersion of times was notably reduced with the consolidated version (SD = 3.35), evidencing more predictable and homogeneous executions among operators.

From these measurements, the study's three indicators were calculated, whose descriptive statistics are presented in Table V. The time reduction index showed a positive difference of 41.00 percentage points, rising from a pre-test mean of 35.42% to a post-test mean of 76.42% with the consolidated version of the application. The operation success rate increased by 23.99 percentage points, from 70.74% to 94.73%. The event traceability level improved by 39.17 percentage points, from 55.02% to 94.19%.

TABLE V. DESCRIPTIVE STATISTICS FOR THE THREE INDICATORS

Indicator	Phase	N	Min	Max	Mean	SD
Ir (%)	Pre-test	30	11.11	56.25	35.42	12.65
Ir (%)	Post-test	30	66.04	86.15	76.42	6.47
TasaE (%)	Pre-test	30	62.86	80.77	70.74	5.05
TasaE (%)	Post-test	30	88.89	97.37	94.73	2.25
NivelT (%)	Pre-test	30	42.42	66.67	55.02	7.00
NivelT (%)	Post-test	30	89.66	97.50	94.19	2.60

The normality analysis using the Shapiro-Wilk test indicated that at least one measurement phase of each indicator did not meet the normality assumption ($p < 0.05$). Consequently, for methodological consistency, the nonparametric Wilcoxon signed-rank test for paired samples was applied in all three cases.

The statistical analysis confirmed significant improvements in the three indicators, with p-values below 0.001 and effect sizes classified as large according to Cohen's criteria. The magnitude of the standardized effect was greatest for the time reduction index, while the success rate and the traceability level showed comparable, albeit slightly smaller, effects. The detailed inferential statistics are summarized in Table VI.

TABLE VI. WILCOXON SIGNED-RANK TEST RESULTS

Indicator	Z	p-value	Effect Size (r)	Interpretation
Ir	-4.782	<0.001	0.873	Large
TasaE	-4.653	<0.001	0.850	Large
NivelT	-4.302	<0.001	0.785	Large

V. DISCUSSION

The results confirm that a web application that orchestrates tasks through Ansible significantly improves the three dimensions of enterprise IT infrastructure operations management. The improvement in time reduction of approximately 41 percentage points is consistent with the evidence that web platforms that automate technical tasks achieve notably faster resolutions than traditional methods [9], [11]. The improvement in the success rate, of approximately 24 percentage points, agrees with business studies reporting significant increases in incident resolution rates after the implementation of web-based systems [12], [13]. The improvement in traceability of approximately 39 percentage points directly addresses the security and auditing dimension that infrastructure performance indicator classifications identify as essential [24]. The large effect sizes (r between 0.785 and 0.873) of the three indicators demonstrate that the improvements are not only statistically significant but also relevant to business operations. It is worth noting that the success rate showed the smallest absolute gain (23.99 percentage points), which is partly explained by a ceiling effect: the pilot version already achieved a baseline performance of 70.74% and, in the post-test, values concentrated near 95%, where residual failures correspond to unreachable hosts or environment unavailability rather than to tool deficiencies; even so, its effect size was large ($r = 0.850$).

The hybrid development methodology that combines the iterative practices of Scrum with the documentary rigor of the Rational Unified Process proved effective for managing the complexity of enterprise infrastructure integrations [32]. The security validation program, which covered authentication, authorization, encryption, input validation, and session management testing, confirmed that the platform meets enterprise-level security requirements for on-premises deployment.

The immutable record of every action—including user, role, resource, and IP address—provides the audit trail that manual procedures could not guarantee, and offers the empirical evidence that studies on digital transformation in the public sector call for to assess progress toward modernization [10], [25].

Several limitations must be acknowledged. The single-group quasi-experimental design limited the ability to draw robust causal inferences, and the generalization of the findings to other corporate contexts is limited; both threats are examined in detail below according to the validity categories. The study was conducted in a development environment using virtual machines; deployment in production under sustained real business load is still pending. Additionally, because the baseline corresponded to the pilot version of the application itself, the measured effects represent the improvement attributable to the consolidation of the system and not the total impact relative to a purely manual process.

To systematize their analysis, the limitations are examined according to the four validity categories customary in empirical software engineering research. Regarding internal validity, the absence of a control group makes it impossible to completely rule out learning or history effects; to mitigate this threat, each operation was first measured with the pilot version as the baseline, and all measurements were automatically recorded in the system database, eliminating manual transcription and observer bias.

Regarding external validity, the results come from a single organization and a controlled development environment that replicated its operating conditions, which limits direct generalization. Nevertheless, the faithful reproduction of the environment—same operating system distributions, network topology, and procedures with IT personnel—favors the transferability of the findings to organizations with similar technological profiles.

Regarding construct validity, the three indicators (Ir, TasaE, and NivelT) operationalize IT operations management through verifiable formulas and ratio scales; however, they do not capture qualitative dimensions such as operator satisfaction or cognitive load, whose incorporation could be addressed in future work.

Finally, regarding conclusion validity, the use of the Wilcoxon test—appropriate for the sample size and the non-normality verified through Shapiro-Wilk—together with the reporting of effect sizes, reduces the risk of erroneous statistical conclusions.

VI. Conclusion and Future Work

This study designed, developed, and functionally validated an on-premises web application that improves the management of enterprise IT infrastructure operations. The application, built on a layered architecture using Ubuntu Server, PostgreSQL 16, Python 3 (Flask), and Ansible as the agentless automation engine, features authentication through the Lightweight Directory Access Protocol (LDAP) of Active Directory, role-based access control, and comprehensive audit logging.

Regarding the specific objectives, the solution increased the time reduction index by approximately 41 percentage points, raised the operation success rate by approximately 24 percentage points, and improved the event traceability level by approximately 39 percentage points. Wilcoxon signed-rank tests confirmed statistically significant improvements in the three indicators (p-values below 0.001, large effect sizes), with Z statistics ranging from -4.782 to -4.302. The detailed inferential results are presented in Table VI. The research went beyond the development of a software tool and provided empirical evidence that the systematic digitalization of enterprise infrastructure operations, adapted to the local corporate context, is a possible path to modernizing the technology industry.

The agentless architecture, validated by recent studies [15], [16], eliminates the overhead of agent management while maintaining scalability. The implementation of role-based access control, grounded in established access control models, ensures that administrative and operational functions remain properly segregated [33]. These findings provide a replicable framework for organizations seeking to modernize their information technology operations using agentless automation platforms.

A promising direction for future development is the implementation of a tiered change-approval workflow for significant infrastructure modifications. When an operator requests a high-impact change, the system could require a mandatory approval step by a user with an administrator profile before the automation playbook is sent to the execution engine. This governance layer aligns with recent frameworks that incorporate risk mitigation and internal controls into information technology operations, guaranteeing that critical changes receive adequate oversight and that accountability is maintained throughout the entire change life cycle [34].

Finally, as a broader extension, the incorporation of artificial intelligence-assisted validation of the Ansible playbooks uploaded to the platform is proposed. This component would automatically analyze files before execution to detect syntax errors, deviations from best practices, and potentially risky configurations, alerting the operator before the task reaches the execution engine. This line of work would connect the platform with recent AIOps trends, where language models and static analysis are combined to increase the reliability of infrastructure automation.

Another improvement involves strengthening the security layer through the integration of two-factor authentication based on time-based one-time passwords, which would further protect the platform against credential compromise. A systematic review of multifactor authentication methods confirms that time-based one-time password schemes remain one of the most practical and effective mechanisms for enterprise systems, and their inclusion complements the existing dual authentication model without disrupting the user experience [35].

***Abstract*—This study examines the impact of gamified escape room activities on student learning performance and engagement in a university-level database design course. A quasi-experimental repeated-measures design was used to compare the traditional learning approach with a gamified escape room incorporating quizzes, points, leaderboards, and nicknames. The gamified escape room featured defined goals, a game character, interactive tasks, immediate feedback, problem-solving challenges, and a fun learning environment. Results from the Wilcoxon Signed-Rank test showed significantly higher post-quiz scores and more consistent performance in gamified escape room-based quiz sessions. User engagement was assessed using the User Engagement Scale (UES), and students reported high levels of focused attention, perceived usability, aesthetic appeal, and reward. These dimensions align with the validated four-factor structure of the UES, which has shown good reliability and applicability across digital contexts. Aesthetic appeal received the highest rating, which implies that visually engaging and interactive design features played an important role in sustaining participation. Student feedback also indicated a strong preference for the gamified approach. These findings support the effectiveness of integrating gamification into classroom learning activities to enhance active learning, engagement, motivation, and knowledge retention.**

***Keywords*—Gamified learning; escape room; quiz; database course; engagement; motivation**

I. Introduction

The rapid advancement of digital technologies has transformed higher education, creating opportunities for innovative teaching approaches that support active and engaging learning experiences. Traditional lecture-based methods are often insufficient to sustain students' attention and participation. Consequently, educators are increasingly adopting student-centered pedagogical approaches that encourage interaction, collaboration, and experiential learning [1]. Among these approaches, gamification has gained prominence as a pedagogical approach to enhance student motivation, engagement, and improve learning outcomes in higher education [2, 3, 4].

Gamification refers to the application of game mechanics, such as points, badges, leaderboards, challenges, rewards and narratives to stimulate participation and improve user experiences [5]. Recent studies [6, 7, 8] have highlighted that gamification is an effective educational approach that encourages learners to solve problems and overcome challenges in game-based environments. Gamification offers innovative strategies to foster active learning and stimulate interest in academic content [9,10]. Inspired by this, escape room-based learning has been increasingly adopted in university settings to promote problem-solving, collaboration, knowledge retention and engagement through immersive and challenge-driven activities [11, 12].

Educational escape rooms transform traditional learning environments into interactive experiences where learners work under time constraints to solve content-related puzzles. These activities incorporate elements such as storylines, clues, and scoring, which have been shown to increase learners' engagement, motivation, and sense of accomplishment [13, 14]. When carefully aligned with learning objectives, such gamified methods can create deeper cognitive engagement, resulting in improved conceptual understanding and performance.

These advantages are particularly relevant to database education. Database courses require students to integrate theoretical knowledge with analytical reasoning and practical implementation while mastering complex concepts such as entity–relationship modelling, normalization, relational database design, SQL programming, and transaction management. Consequently, students frequently perceive database courses as abstract, cognitively demanding, and difficult to understand. While conventional paper-based quizzes remain a common method of content reinforcement, they often lack the dynamic interaction and immediacy that digital and game-enhanced activities can offer. To address these challenges, several studies have introduced gamification into database education. Schildgen [11] proposed MonsTER Park, an online educational game for learning Entity-Relationship Diagrams.

Universiti Malaysia Sarawak and UNIMAS Scholarship of Teaching and Learning Research Grant (UNI/F08/SoTL-RG/85796/2023)

The study revealed that students enjoyed the game and did not encounter any difficulties in completing the tasks. However, the study did not explore the effectiveness of MonsTER in increasing students' learning engagement. Similarly, Dæhli et al. [12] developed a web-based tool known as LearnER to teach basic data modeling skills. The study demonstrated that the use of gamification elements such as earning points and a high score list in the LearnER tool significantly motivated the students and contributed to their learning of the data modeling course. The study reported that some students need more precise information on how to earn more points. Another important insight from the study is that more advanced game mechanics would further motivate the data modeling learning engagement process. In addition, the use of interactive digital learning environments has demonstrated positive educational impacts. For example, Deng et al. [13] found that Pencil Code, a web-based programming platform, significantly improved students' computational thinking skills and computer learning attitudes, highlighting the potential of technology-enhanced and interactive learning environments to foster deeper learner engagement and positive learning experiences. Furthermore, Barra et al. [14] investigated the use of a remote educational escape room for database learning across four higher education courses over two academic years. Using pre- and post-tests, student perception questionnaires, and learning analytics collected through a web platform, the study demonstrated that remote educational escape rooms were both engaging and effective for teaching database concepts. Students reported high levels of enjoyment, immersion, and satisfaction, with more than 95% recommending that similar activities be incorporated into other courses. The findings suggest that educational escape rooms provide an effective approach for reinforcing theoretical database concepts while simultaneously developing collaborative problem-solving skills.

Although gamification has been explored in various academic contexts, limited research has focused on the effects of escape room-based quizzes on learning performance and engagement in university-level computer database courses. Database knowledge is essential in IT education. The database course was one of five information technology pillars in the 2008 ACM/IEEE Curriculum Guidelines for Undergraduate Degree Programs in Information Technology [15]. Furthermore, the most recent version of the ACM/IEEE Computer Society Task Group on Information Technology Curricula (2017) includes data modeling and database query languages as essential IT topics in information management [16].

Therefore, this study addresses the gap by evaluating how traditional and gamified escape room-based quiz learning activities influence students' post-lecture performance and their perceptions of learning within a database design course. Specifically, the study aims to examine the effectiveness of employing a gamified escape room on students' learning performance and engagement. To evaluate students' engagement levels, the User Engagement Scale (UES) was adopted as a measurement instrument to assess dimensions such as focused attention (FA), perceived usability (PU), aesthetic appeal (AE), and reward (RW). By incorporating both learning performance and engagement measures, this study provides a more comprehensive understanding of the effectiveness of gamified learning activities in database education.

To guide this investigation, the primary research questions are formulated:

- Is there any significant difference in students' learning performance between paper-based quizzes and gamified escape room-based quizzes?
- To what extent do gamified escape room activities promote student engagement in terms of FA, PU, AE, and RW?

The main contributions of this study are twofold. First, the study provides empirical evidence on the effectiveness of gamified escape room-based quizzes in improving students' learning performance compared with traditional paper-based quizzes. The Wilcoxon Signed-Rank test results demonstrate significant improvement in students' post-lecture performance, which implies the effectiveness of gamified escape room activities as an active learning approach. Second, the study evaluates student engagement with the gamified escape room using the UES across four dimensions: FA, PU, AE, and RW. The findings reveal high levels of engagement across all four dimensions, with aesthetic appeal receiving the highest rating. This demonstrates that the gamified escape room provides an engaging and positive learning experience for students.

II. Material and Methods

A. Participants and Setting

The participants in this study were 200 undergraduate students enrolled in a Database Design course at a Malaysian higher education institution. All participants were aged between 18 and 26 years old. Before the study began, all students were briefed on the study's objectives and procedures and provided informed consent. The learning sessions took place in a face-to-face classroom setting and incorporated two types of structured learning activities: traditional paper-based quizzes and gamified escape room-based quizzes (gamified ER-based quizzes). These quizzes were not graded in the course assessment and were used purely as active learning tools to reinforce students' understanding of the lecture content and support knowledge retention.

B. Learning Tools

Traditional Quizzes: These were paper-based quizzes consisting of multiple-choice questions (MCQs) designed to assess students' understanding of key concepts presented during the lectures.

Gamified Escape Room Quizzes: These quizzes were delivered through an interactive digital escape room platform. Students solved a series of MCQ quizzes and challenges based on the lesson content. Elements of gamification such as leaderboards, badges, points, scores, and nicknames were embedded to enhance the student learning experience and motivation.

C. Study Design

This study employed a quasi-experimental repeated-measures design conducted over a period of four consecutive weeks. The same group of students participated consistently throughout the intervention. Fig. 1 illustrates the four-week study design combining lectures, quizzes, and gamified activities. Each week consisted of a scheduled face-to-face lecture accompanied by a pre-lecture and post-lecture quiz.

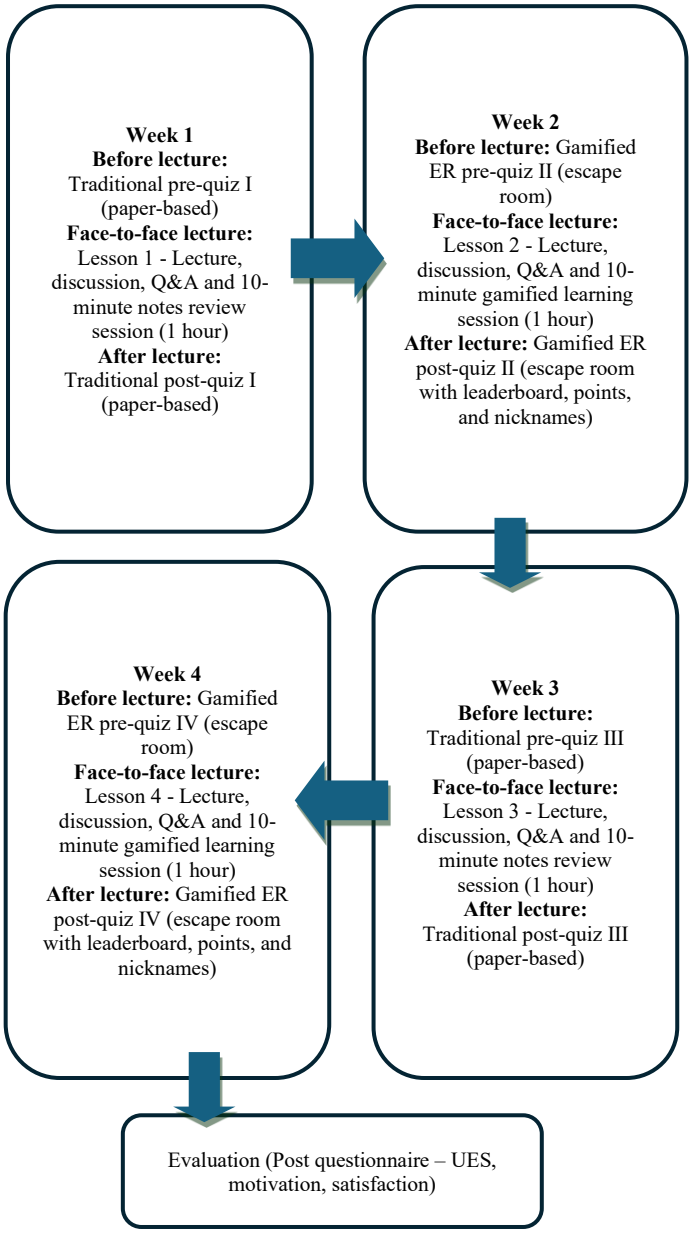

Fig. 1. Study design.

The pre- and post-quizzes alternated between traditional paper-based and gamified ER-based quizzes across the weeks to allow comparison. The quizzes were designed to have comparable levels of difficulty across both formats. Quantitative data were collected from the pre- and post-quiz scores to measure students' learning performance.

In addition, a post-intervention questionnaire was conducted after the Gamified ER post-quiz IV (Week 4) to evaluate student engagement and satisfaction across the different learning tools. The learner engagement data were also collected using the adapted User Engagement Scale (UES) developed by O'Brien et al. [17]. The UES assesses engagement across four constructs: Focused Attention (FA), Perceived Usability (PU), Aesthetic Appeal (AE), and Reward Factor (RW). The items were measured using a 5-point Likert scale ranging from strongly disagree to strongly agree. The collected evaluation data were analysed using descriptive statistics to summarise engagement levels across the UES dimensions. Furthermore, the reliability of the adapted UES was evaluated using Cronbach's alpha, following the approach adopted by Amriza et al. [18].

III. Gamified Platform

A. Gamification Elements

Building on previous research that identified common gamification elements in educational settings [15, 19, 20], this study integrated several features to boost student motivation and engagement. Specifically, the gamification elements included a leaderboard, escape room challenge, background music, points system, and digital certificates. These features were embedded within the gamification learning platform and deployed during the in-class gamified ER-based quiz sessions. The escape room activity served as the core interactive component, where students solved database subject-related challenges. Background music, which could be turned on or off by the students, provided an immersive and stimulating environment. Points were awarded based on task completion and accuracy, and students' cumulative scores were reflected in a dynamic leaderboard visible to all participants. This encouraged healthy competition among peers. To preserve anonymity and promote fairness, students participated under nicknames rather than real names. At the end of the session, students received digital certificates as recognition of their performance. Their ranking position and the top three scores remained visible on the gamification learning platform until the next scheduled activity to provide sustained motivation and a sense of accomplishment.

B. Gamified Learning Session

As illustrated in Fig. 2 and Fig. 3, the gamified learning session was designed as an engaging learning activity to reinforce key concepts covered in the database course. The session consisted of 10 interactive questions delivered through a game-based interface. The question types varied and included MCQs, true or false, and fill-in-the-blank formats. This variety aimed to support content recall and conceptual understanding through active participation. The interface featured a visually immersive environment with game-like elements such as a score tracker and a themed background. The session served as a preparatory activity before students advanced to the escape room quiz, which offered further opportunities to apply their knowledge in a more challenging and problem-solving context.

Fig. 2. Gamified learning platform.

Fig. 3. Gamified learning question.

C. Escape Room

The escape room approach in education is a modern pedagogical strategy designed to motivate students through immersive and interactive learning experiences. Prior studies have demonstrated its effectiveness in enhancing learning across subjects such as Mathematics [21,22]. Drawing inspiration from these, the gamified escape room in this study integrates goal-setting, game characters, interactive tasks, feedback, problem-solving, and a fun learning environment.

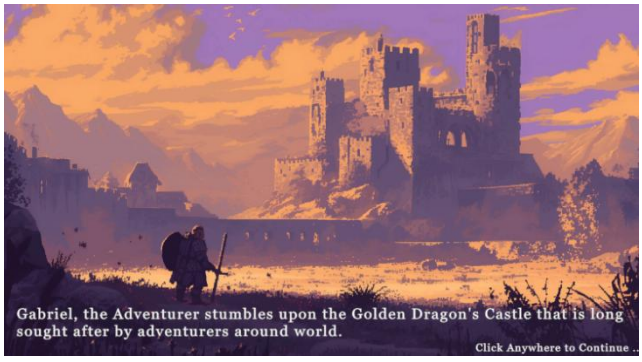

Fig. 4. Gabriel, the adventurer, enters the castle to seek treasure.

As illustrated in Fig. 4, the storyline begins with Gabriel, the adventurer, entering the Golden Dragon's Castle in search of treasure. Students solve database challenges to help Gabriel progress through the escape room adventure.

Fig. 5. Escape Room (ER) page.

Fig. 5 shows the escape room setting where learners engage with the environment to unlock clues and progress in the game. Each challenge is tied to database concepts, encouraging students to analyze clues, recall lesson content, and apply knowledge in a meaningful way, which mirrors the real-world problem-solving in database design (see Fig. 6). After completing each challenge, students receive a clue that helps them unravel the final escape code.

Fig. 6. Gamified ER-based quiz.

IV. Results

A. Student Learning Performance

The findings of this study reveal that the gamified escape room learning activity significantly enhanced students' learning performance compared to the traditional paper-based quiz activity. All students participated in both activities, enabling a within-subject comparison of their performance.

TABLE I. Wilcoxon Signed-Rank Test for Comparing Students' Achievements Between Paper-Based and Gamified Escape Room-Based Post-Quizzes

Quizzes	N	Wilcoxon Signed-Rank Test			
		Mean	*W-value*	*z-score*	*p-value*
Paper-based quiz I	200	80.58	172.50	10.85	< .001
Gamified ER-based quiz II	200	98.67			
Paper-based quiz III	200	85.17	0.00	9.42	< .001
Gamified ER-based quiz IV	200	99.83			

As shown in Table I, the Wilcoxon Signed-Rank test results indicated statistically significant differences in student scores between the two types of learning activities. Following the face-to-face lecture in Lesson 1, which included a lecture, discussion, question-and-answer session, and a short 10-minute notes review, students completed the Paper-based Post-Quiz I. The mean score obtained for this post-quiz was 80.58. In contrast, in Week 2, the face-to-face lecture for Lesson 2 incorporated a 10-minute gamified learning session, discussion, and question-and-answer activities, followed by gamified ER Post-Quiz II. The mean score increased to 98.67, which was significantly higher than the paper-based Post-Quiz I mean score of 80.58 ($W = 172.50$, $z = 10.85$, $p < .001$). A similar trend was observed in Weeks 3 and 4, where the paper-based Post-Quiz III (Lesson 3) produced a mean score of 85.17, whereas the gamified ER Post-Quiz IV achieved a significantly higher mean score of 99.83 ($W = 0$, $z = 9.42$, $p < .001$).

On average, students completed the escape room challenge in approximately six minutes. These results underscore the added instructional value of combining gamified learning with interactive activities like escape rooms, compared to traditional passive review.

TABLE II. COMPARISON OF STUDENTS' PRE- AND POST-QUIZ PERFORMANCE FOR PAPER-BASED AND GAMIFIED ESCAPE ROOM-BASED QUIZZES

Quizzes	N	Pre-Quiz			Post-Quiz		
		Mean	*SD*	*Mdn*	*Mean*	*SD*	*Mdn*
Paper-based quiz I	200	23.83	16.71	16.67	80.58	16.31	83.33
Gamified ER-based quiz II	200	27.58	16.21	33.33	98.67	4.52	83.33
Paper-based quiz III	200	25.25	15.9	16.67	85.17	14.79	100
Gamified ER-based quiz IV	200	34.42	14.15	33.33	99.83	1.66	100

Further evidence can be seen in the pre- and post-quiz descriptive statistics in Table II. Students began with similar pre-quiz medians (16.67 to 33.33), reflecting comparable baseline knowledge. After the learning sessions, post-quiz medians increased substantially, reaching 83.33 for both Quiz I and Quiz II, and 100 for Quiz III and Quiz IV. Additionally, the standard deviations were lower in the gamified ER-based quiz activities (e.g., SD = 4.52 for Quiz II and 1.66 for Quiz IV), indicating more consistent performance, possibly due to the motivational and interactive elements embedded in the gamified learning environment.

These quantitative findings were further reinforced through student perceptions. All respondents expressed high levels of satisfaction with escape room learning and recommended it as a supplementary tool for juniors in database courses. All students indicated a preference for the gamified ER-based quizzes approach over the conventional paper-based quizzes. They cited its greater satisfaction, motivation and effectiveness during class activities. This makes us believe that interactive and gamified learning is not just effective in terms of academic performance but is also well-accepted and pedagogically impactful.

B. Student Engagement and Experience

After the gamified ER post-quiz IV, all participants completed the UES O'Brien et al. [17] to evaluate their experience with the gamified ER-based quiz activities (see Appendix- Table VI). The questionnaire items use a 5-point Likert scale (1 "Strongly Disagree" to 5 "Strongly Agree"). The UES evaluates four engagement dimensions: Focused Attention (FA), Perceived Usability (PU), Aesthetic Appeal (AE), and Reward (RW).

To assess the UES evaluation results, the response values for the UES items PU.1, PU.2, PU.3, PU.4, PU.5, PU.6, PU.8, and RW.3 were reverse-coded before analysis [23]. Then, descriptive statistics were calculated to summarize participants' responses for each item, including the mean, standard deviation (SD), minimum, median, maximum, and mode. As shown in Table III, the mean scores across all constructs were high, ranging from 4.41 to 4.74. These high mean scores indicate a high level of student engagement with the Gamified ER-based quiz activities. Most items also recorded a mode of 5, in which the majority of participants strongly agreed with the statements related to engagement, usability, visual appeal, and perceived reward for the activity. These findings suggest that the gamified escape room design effectively supported active participation, high engagement, and positive learning experiences among students.

TABLE III. DESCRIPTIVE STATISTICS OF UES EVALUATION RESULTS (N = 200). ITEMS WERE RATED ON A 5-POINT LIKERT SCALE (1 = STRONGLY DISAGREE, 5 = STRONGLY AGREE)

UES	*Mean*	*SD*	*Min*	*Mdn*	*Max*	*Mode*	*N for Mode*
FA.1	4.69	0.46	4	5	5	5	138
FA.2	4.62	0.62	2	5	5	5	133
FA.3	4.61	0.62	2	5	5	5	132
FA.4	4.61	0.67	2	5	5	5	135
FA.5	4.56	0.74	2	5	5	5	132
FA.6	4.61	0.57	2	5	5	5	128
FA.7	4.6	0.63	2	5	5	5	129
PU.1	4.53	0.58	2	5	5	5	113
PU.2	4.41	0.67	2	4	5	5	97
PU.3	4.44	0.6	2	4	5	4	100
PU.4	4.46	0.6	2	5	5	5	100
PU.5	4.49	0.6	2	5	5	5	106
PU.6	4.49	0.57	2	5	5	5	103
PU.7	4.61	0.59	2	5	5	5	129
PU.8	4.46	0.6	2	4	5	5	99
AE.1	4.74	0.44	4	5	5	5	147
AE.2	4.71	0.45	4	5	5	5	142
AE.3	4.69	0.55	2	5	5	5	144
AE.4	4.68	0.56	2	5	5	5	143
AE.5	4.63	0.55	2	5	5	5	131
RW.1	4.46	0.68	2	5	5	5	105
RW.2	4.64	0.49	3	5	5	5	128

RW.3	4.45	0.61	2	4	5	5	99
RW.4	4.59	0.63	2	5	5	5	128
RW.5	4.66	0.57	2	5	5	5	139
RW.6	4.68	0.58	2	5	5	5	143
RW.7	4.64	0.54	2	5	5	5	131
RW.8	4.68	0.5	2	5	5	5	137
RW.9	4.63	0.54	2	5	5	5	130
RW.10	4.67	0.56	2	5	5	5	139

Note: SD = standard deviation; Min = minimum; Mdn = median; Max = maximum

C. Reliability Analysis and Descriptive Statistics

Reliability analysis and descriptive statistics were conducted to assess the reliability of each UES scale. As shown in Table IV, all constructs demonstrated good internal consistency, with Cronbach's alpha values ranging from 0.840 to 0.913. The mean scores for the UES scales were also relatively high, ranging from 4.484 to 4.689. Among the dimensions, AE recorded the highest mean score (Mean = 4.689), followed by RW (Mean = 4.607), FA (Mean = 4.612), and PU (Mean = 4.484). These results suggest that students perceived the gamified ER activity as visually appealing, rewarding, and capable of sustaining their attention. The relatively small standard deviations further indicate that the responses were consistent across participants. Overall, the findings show positive student engagement in the gamified ER activity. It also demonstrates that the UES scales are reliable measures for evaluating different dimensions of student engagement.

D. Validity Analysis

Exploratory Factor Analysis (EFA) and Confirmatory Factor Analysis (CFA) were further conducted to examine the factor structure. As shown in Table V, the results supported a four-factor model consisting of FA, PU, AE, and RW. All factor loadings were high and statistically significant ($p < .001$), indicating that the UES questionnaire is a reliable instrument for measuring student engagement in the gamified ER environment.

TABLE IV. RELIABILITY ANALYSIS AND DESCRIPTIVE STATISTICS

UES	No Items	Cronbach's Alpha	Mean	Standard Deviation
Focused Attention (FA)	7	0.840	4.612	0.445
Perceived Usability (PU)	8	0.913	4.484	0.476
Aesthetic Appeal (AE)	5	0.903	4.689	0.438
Reward (RW)	10	0.881	4.607	0.399

TABLE V. FACTOR LOADINGS OF THE GAMIFIED ER WITH 1-FACTOR EXPLORATORY MODEL AND WITH 4-FACTOR CONFIRMATORY MODEL

Factor		Exploratory Factor Analysis (EFA)	4-factor Confirmatory Factor Analysis (CFA)					
			FA	*PU*	*AE*	*RW*	*z-score*	*p-value*
Focused Attention (FA)	FA.1	0.850	0.869				25.805	< .001
	FA.2	0.921	0.861				31.983	< .001
	FA.3	0.893	0.796				23.726	< .001
	FA.4	0.810	0.757				18.748	< .001
	FA.5	0.858	0.827				25.073	< .001
	FA.6	0.684	0.879				30.290	< .001
	FA.7	0.607	0.860				25.901	< .001
Perceived Usability (PU)	PU.1	0.849		0.830			28.275	< .001
	PU.2	0.893		0.871			40.602	< .001
	PU.3	0.953		0.953			63.849	< .001
	PU.4	0.920		0.975			56.664	< .001
	PU.5	0.921		0.925			49.931	< .001
	PU.6	0.883		0.926			53.988	< .001
	PU.7	0.467		0.567			8.716	< .001
	PU.8	0.891		0.855			34.431	< .001
Aesthetic Appeal (AE)	AE.1	0.874			0.951		63.424	< .001
	AE.2	0.872			0.937		59.547	< .001
	AE.3	0.961			0.951		70.568	< .001
	AE.4	0.913			0.952		47.846	< .001
	AE.5	0.936			0.957		64.474	< .001
Reward (RW)	RW.1	0.570				0.636	13.771	< .001
	RW.2	0.923				0.924	46.104	< .001

	RW.3	0.519				0.653	14.906	< .001
	RW.4	0.872				0.852	30.538	< .001
	RW.5	0.785				0.778	25.107	< .001
	RW.6	0.805				0.757	21.714	< .001
	RW.7	0.884				0.873	35.082	< .001
	RW.8	0.880				0.900	47.036	< .001
	RW.9	0.905				0.921	44.950	< .001
	RW.10	0.903				0.906	39.562	< .001

V. DISCUSSION

These findings are consistent with previous research highlighting the benefits of gamified instructional approaches in higher education settings. Zainuddin et al. [24] emphasized that integrating interactive and competitive elements through gamification can enhance learning outcomes. In the present study, the use of escape room–based quizzes enabled students to engage with database concepts in a simulated and challenge-driven environment that mirrored active learning principles. The gamified activities likely helped students score higher in both gamified sessions (Quiz II and Quiz IV). This pattern was also observed in a similar study by Gordillo and López-Fernández [25], which demonstrated increased knowledge acquisition and improved student perceptions in software engineering education through escape rooms.

The reduced standard deviations in the gamified ER-based quiz results (SD = 4.52 and 1.66) suggest that students performed more consistently compared to the traditional paper-based quizzes. This indicates that the escape room may have been particularly effective in supporting students who typically struggle in conventional learning settings. By embedding course content within an interactive game scenario that included points, nicknames, feedback, and leaderboards, the learning activities promoted motivation and knowledge retention. This finding is consistent with Welbers et al. [26], who demonstrated the potential of gamification to enhance student engagement in learning activities. Recent work by Mauri-Medrano et al. [27] also found that students exposed to escape room learning showed increased levels of fun and creative thinking that align closely with our observed results.

Aligned with the work of Lampropoulos and Kapoula [28] and Gerber and Fischetti [29], these findings reinforce the value of gamification in transforming passive content delivery into interactive and problem-solving experiences. In this study, the escape room tasks were designed to reflect core learning objectives from the database course, complemented by a short gamified learning session before the ER quizzes. Furthermore, students received immediate feedback during the gamified escape room activities and could identify errors in their responses. The paper-based quizzes did not provide this immediate feedback. This learning activity likely enhanced student motivation and knowledge retention, as reflected in the significantly higher post-quiz means from the gamified ER-based sessions (98.67 and 99.83) compared to the paper-based counterparts (80.58 and 85.17).

Moreover, the students' feedback obtained during Week 4 further supports the quantitative results. All students reported being very satisfied with the Escape Room activity and recommended it for future use. The preference of all students towards the gamified method rather than the paper-based quiz reflects its perceived effectiveness and demand in enhancing classroom learning activities.

Furthermore, the students reported high engagement across all UES dimensions. The elements in the gamified ER, such as leaderboards, nicknames, and points, likely increased students' motivation and active participation. This finding is consistent with Wiebe et al. [30], in which the work reported that higher engagement levels in game-based environments are associated with improved performance outcomes.

In summary, these outcomes support the use of escape rooms integrated with gamification concepts as an effective pedagogical tool. In addition to reinforcing conceptual understanding, this approach also fosters student motivation and encourages equitable participation, which are important contributors to academic success and sustained motivation in learning.

VI. CONCLUSION

This study demonstrates that gamified ER-based quiz activities can significantly enhance students' learning performance, motivation, and engagement in higher education, particularly in content-intensive subjects like database design. The within-subject design allowed students to experience both traditional and gamified approaches, and the results clearly showed higher post-quiz scores in the gamified sessions. The integration of game elements such as points, nicknames, and leaderboards provided an engaging, competitive, and immersive environment that supported knowledge retention and active learning. The user experience findings also indicate that students responded positively to both the practical and experiential aspects of the activity. High ratings for focused attention, perceived usability, aesthetic appeal, and reward are in line with the established four-factor structure of the UES, which has been shown to have good reliability and validity. Aesthetic appeal received the strongest evaluation, suggesting that visually appealing and interactive design features play an important role in sustaining engagement. This fits prior research showing that aesthetic appeal is one of the most stable engagement dimensions, while enjoyable and activating escape-room experiences are consistently associated with stronger student participation and positive learning perceptions. Moreover, the consistent preference for the gamified quizzes over traditional methods highlights the effectiveness of interactive learning designs in fostering student participation and a high level of engagement. These findings are consistent

with previous research, which supports the use of gamification as an effective pedagogical tool for enhancing student engagement. They align with the growing need to transform conventional assessments into dynamic learning experiences that encourage self-directed learning. Therefore, educators are encouraged to explore and implement gamified strategies like escape rooms to enrich instructional delivery, improve learning outcomes, and support 21st-century educational goals.

VII. Limitations and Future Work

This study was conducted among undergraduate students enrolled in a database course at a single institution, which limits the generalizability of the findings. Future research should involve multiple institutions and educational contexts to examine the broader applicability of the gamified escape room approach. Longer-term studies could assess its effects on knowledge retention and sustained student engagement. Future research could also examine the individual contributions of immediate feedback, points, and leaderboards to determine which elements most effectively support learning.

Acknowledgment

The authors acknowledge the UNIMAS Scholarship of Teaching and Learning Research Grant (UNI/F08/SoTL-RG/85796/2023) and Universiti Malaysia Sarawak for supporting this project. We also thank Neoh Jin Ming for developing the application and providing technical support.

TABLE VI. UES ITEMS

Item	UES
AE.1	This Application X was attractive.
AE.2	This Application X was aesthetically appealing.
AE.3	I liked the graphics and images of Application X.
AE.4	Application X appealed to my visual senses.
AE.5	The screen layout of Application X was visually pleasing.
FA.1	I lost myself (deeply focused) in this experience.
FA.2	I enjoyed the experience of using Application X that I lost track of time.
FA.3	I blocked out activities around me when I was using Application X.
FA.4	When I was using Application X, I lost track of the world around me.
FA.5	The time I spent using Application X just slipped away.
FA.6	I was absorbed (interested) in this experience.
FA.7	During this experience I let myself enjoy it.
PU.1	I felt frustrated while using this Application X.
PU.2	I found this Application X confusing to use.
PU.3	I felt annoyed while using Application X.
PU.4	I felt discouraged while using this Application X.
PU.8	I could not do some of the things I needed to do while using Application X.
PU.5	Using this Application X was tiring.
PU.6	This experience of Application X browsing is troublesome.
PU.7	I felt in control while using this Application X.
RW.1	Using Application X was worthwhile.
RW.2	I consider my experience a success.
RW.3	This experience did not work out the way I had planned.
RW.4	My experience was rewarding.
RW.5	I would recommend Application X to my peers and friends.
RW.6	I continued to use Application X out of curiosity.
RW.7	The content of Application X sparked my interest.
RW.8	I am really interested into this experience.
RW.9	I felt involved in this experience.
RW.10	This experience was fun.

Fall Detection System Using Accelerometer and Gyroscope Sensors with Backpropagation Neural Networks

***Abstract*—A fall is an incident in which a person suddenly loses their balance and falls uncontrollably to the ground or another surface. This is particularly dangerous for the elderly, as it can lead to serious injury or even death if not treated immediately. This study suggests utilizing a Backpropagation Neural Network (BPNN) to classify fall and non-fall incidents, particularly in older adults, by measuring alterations in linear acceleration and angular velocity obtained from accelerometer and gyroscope sensors. A dataset featuring eight distinct movement types, including standing to bowing, standing to squatting, sitting to standing, standing to prostrating, sitting to prostrating, falling sideways, falling forward, and falling backward, is collected from 69 participants and processed by determining the difference (Δ) between consecutive sensor measurements, followed by normalization, labeling, and statistical feature extraction. The collected features are fed into a BPNN that has two hidden layers, each with 64 and 128 neurons. The proposed model achieved an accuracy of 86.87%, validation accuracy of 85.00%, and testing accuracy of 92.86%. Furthermore, test results show a precision of 94%, recall of 85%, and specificity of 97%, demonstrating the system's ability to accurately classify eight different human activities and distinguish falls from normal daily activities. These findings indicate that a Backpropagation Artificial Neural Network in conjunction with the suggested Δ-based preprocessing offers an efficient method for inertial sensor-based fall detection systems.**

***Keywords*—Backpropagation neural network; fall detection; human activity recognition; accelerometer; gyroscope**

I. Introduction

Patient safety is of utmost importance, and falls are among the most frequent incidents affecting elderly adults. For elderly patients, experiencing unnoticed falls can pose a hidden danger. The immediate consequences of a fall, such as injury, can be worse if assistance is not obtained immediately. Statistics indicate that the most serious outcomes result from delays in receiving help and medical care, rather than from the fall itself [1-4].

In the healthcare sector, the development of fall detection devices has become a prominent research topic. Recent advancements in Micro-Electro-Mechanical Systems (MEMS) sensor and actuator technology have enabled the development of fall detection systems using accelerometers and gyroscopes [5-8]. This technique relies on detecting and tracking changes in acceleration along three orthogonal directions to identify changes in a person's body position and movement. A threshold-based fall detection system uses wearable sensors to detect sudden body movements. The system monitors when total acceleration exceeds a pre-set numerical threshold value. If the data surpasses that limit, the system flags a potential fall event [9-12]. The collected data is continuously analyzed algorithmically to determine whether the individual has fallen. If a fall is detected, the device can use GPS and a wireless transmitter to determine the location and issue an alert for help. Research has also been conducted on fall detection using smartphone accelerometers, where the system can send an SMS containing an alert message indicating that the patient has fallen, along with the person's coordinates, and automatically connect the call to a pre-registered number [13-16]. The core elements of fall detection are reliable detection principles and practical algorithms for assessing the existence of emergencies.

Various classification methods have been applied to improve the accuracy of fall detection. Research using the Fuzzy Logic method has been able to detect falls based on a rule base constructed from changes in acceleration values and body orientation. However, the performance of this method is highly dependent on the formulation of rules and membership functions, making it less flexible in recognizing complex movement variations [17-20]. Another study using the K-Nearest Neighbor (KNN) algorithm showed that accelerometer and gyroscope data can be classified with a good level of accuracy, but its performance is influenced by the choice of the K value, the distribution of the training data, and increased computation time as the dataset size grows [21-23].

Addressing these issues, this study develops an activity classification and fall detection model using a Backpropagation Neural Network that utilizes accelerometer and gyroscope data from the MPU6050 sensor. This study employs a relatively large dataset—comprising 36,432 data points collected from 69 participants—covering eight types of movements: standing to bowing, standing to squatting, sitting to standing, standing to prostrating, sitting to prostrating, falling sideways, falling forward, and falling backward. Furthermore, the study implements preprocessing stages—including the calculation of inter-sample value changes (Δ), normalization, and data labeling—prior to the training process to generate more representative features. The primary contribution of this

Higher Education for Technology and Innovation (HETI) Project.

research is the development of a Backpropagation Neural Network model that utilizes a larger dataset and comprehensive preprocessing steps to enhance the classification performance for these eight movement types based on MPU6050 sensor data. Model performance is evaluated using a confusion matrix based on accuracy, precision, recall, and specificity metrics to assess the ability of the model to accurately recognize activities and detect falls [24-26].

The following sections of this study are organized as follows: Section II presents the stages of this research and proposes the backpropagation neural network architecture employed. Model training and the discussion of test results are presented in Section III. Finally, research findings are concluded in Section IV.

II. METHOD

This study aims to develop a fall detection system utilizing accelerometer and gyroscope sensors integrated into an MPU6050 module. An Artificial Neural Network (ANN) employing the backpropagation method is used to process sensor data and identify various movement patterns, thereby distinguishing between falls and normal daily activities.

Fig. 1 shows the workflow of the research methodology. In the initial phase of the research, the MPU6050 module, comprising accelerometer and gyroscope sensors mounted on a wearable vest, is used to collect data. These sensors continuously recorded movement data from subjects performing various movement scenarios, including simulated falls and daily activities. The collected raw signals subsequently underwent preprocessing to remove noise and normalize the data, ensuring uniformity for further analysis.

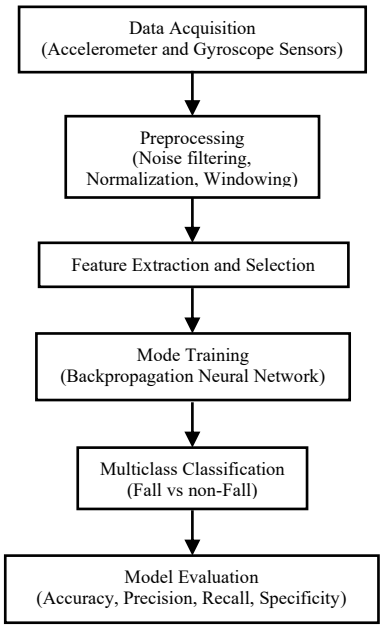

Fig. 1. Research stages of a fall detection system using a Backpropagation Neural Network (BPNN).

Following preprocessing, pertinent movement characteristics that characterize various movement patterns are obtained using a feature extraction and selection process. A BPNN model is then trained using the backpropagation algorithm utilizing the chosen features as input. The data set is split into training and testing subsets in order to assess the model performance and guarantee cross-validation of the classification procedure. The BPNN architecture is optimized by varying the number of hidden layers and neurons to achieve the highest accuracy. Model performance is evaluated based on accuracy, precision, recall, and specificity.

The following part provides a detailed description of how the proposed fall detection system is implemented.

A. Data Collection

The dataset in this study is collected using primary data acquisition from subjects wearing a vest equipped with the MPU6050 sensor module, which combines a 3-axis accelerometer and a 3-axis gyroscope. This sensor is placed on the user's shoulder and operated via an Arduino-based system. This placement is chosen to capture movement data and changes in body orientation with greater accuracy, given that the shoulder area is relatively stable and less prone to the extraneous movements often associated with the arms or legs. Thanks to this consistent and stable positioning, the sensor can measure angular changes and body movements with a higher degree of precision. Furthermore, the shoulder surface, which tends to remain relatively parallel to the earth, helps enhance measurement accuracy while minimizing interference caused by unexpected movements.

The dataset consists of motion signals recorded from simulated fall events as well as normal daily activities. In this research, the dataset was collected from 69 participants, where data from 62 participants are used for model training and data from the remaining 7 participants are used for model testing. Each participant took part in a data collection session covering two types of movements: non-fall movements (standing to bowing, standing to squatting, sitting to standing, standing to prostrating, and sitting to prostrating) and fall movements (falling sideways, falling forward, and falling backward). Conducting fall experiments on older adults entails certain risks, even under controlled settings; therefore, the fall simulations for this study were conducted exclusively and in a controlled manner on young participants between the ages of 20 and 24.

In order to gain coherent movement patterns, each activity is recorded from the initial position to the final position of the movement. Specifically for simulated fall activities, the recording process begins when the subject is in an upright position, continues as the subject loses balance, and concludes when the subject reaches the final position after the fall. This series of stages is carried out to fully represent the fall movement pattern, which will subsequently be used as input data for the BPNN. An illustration of the data acquisition process when a participant experiences a fall is shown in Fig. 2. The complete dataset is then split into training and testing subsets to evaluate the model performance.

Fig. 2. Illustration of data collection from a subject who has experienced a fall.

B. Preprocessing and Feature Selection

Raw data obtained from sensors undergoes a preprocessing stage to enhance its quality and consistency. These preprocessing steps include noise filtering, normalization, and the segmentation of time-series signals into windows suitable for feature extraction. This stage ensures uniform data scaling and minimizes measurement errors, rendering the data more suitable for analysis using an ANN. Data is measured and recorded using an MPU6050 sensor, which yields six parameters: acceleration (Ax, Ay, and Az) and angular velocity (Gx, Gy, and Gz) along the x, y, and z axes, respectively. Feature extraction and selection are carried out to identify motion characteristics most relevant to fall detection. Each activity is recorded over 11 samples, so that each movement produced an 11 x 6 data matrix representing changes in acceleration and body orientation throughout the activity, as presented in Table I.

TABLE I. RAW DATA FROM ACCELEROMETER AND GYROSCOPE SENSOR READINGS BEFORE PREPROCESSING

No	Accelerometer (A)			Gyroscope (G)		
	Ax	Ay	Az	Gx	Gy	Gz
1	-1.60	-3.70	8.52	0.09	0.09	-0.24
2	-1.66	-3.71	8.51	0.64	0.49	-1.19
3	-1.53	-3.76	8.49	0.99	0.05	-4.84
4	-1.47	-3.70	8.53	-0.17	-0.40	0.40
5	-1.53	-3.71	8.53	-1.59	-3.97	-0.96
6	-1.79	-3.60	7.29	-19.73	-57.05	-12.08
7	6.93	-4.36	3.65	-24.90	-103.53	-35.62
8	9.94	-4.41	-1.97	-5.69	-53.59	-24.87
9	9.79	-3.29	-3.38	0	-0.95	-7.31
10	8.75	-3.52	-2.78	4.18	-0.12	-1.37
11	9.05	-3.32	-2.91	1.98	-0.98	-1.34

Before being used as input for the BPNN model, the data undergoes preprocessing steps that include dataset preparation, calculation of the change in values between samples (Δ), normalization, and data labeling. After the raw data is obtained, the next step is to calculate the difference (Δ) between samples for each parameter of the accelerometer (Ax, Ay, and Az) and the gyroscope (Gx, Gy, and Gz). This calculation aims to represent the changes in acceleration and angular velocity that occur during the activity, so that movement characteristics can be captured more accurately than when using raw sensor values. Additionally, using the Δ values helps reduce the influence of differences in the initial sensor positions among participants. Since each activity consists of 11 samples, the Δ calculation process yields 10 data points for each sensor parameter, which are then used as input features in the Backpropagation Neural Network model as presented in Table II.

Based on the calculated change values (Δ), each data point is then labelled according to the type of activity performed. The labelling process aims to distinguish eight movement classes: standing to bowing, standing to squatting, sitting to standing, standing to prostrating, sitting to prostrating, falling sideways, falling forward, and falling backward. The data that has undergone the change value calculation and labelling processes is then used as input for the feature extraction stage and the training of the BPNN.

TABLE II. SAMPLE OF DIFFERENCE (Δ) VALUES OBTAINED FROM ACCELEROMETER AND GYROSCOPE DATA

No	Accelerometer (A)			Gyroscope (G)

C. Modelling

In the modelling phase, the classification process is carried out using an ANN trained with the backpropagation algorithm. The model training process is implemented using the Python programming language, which offers flexibility in optimizing network parameters. Before the training process begins, each parameter representing the change (Δ) is transformed into statistical features consisting of the minimum (Min), maximum (Max), mean (Mean), and standard deviation (Standard Deviation) values [27-29]. This feature extraction process summarizes the key characteristics of each activity, reducing data complexity while preserving essential information that represents movement patterns. The minimum and maximum values represent the lowest and highest sensor readings during the activity, respectively; the mean value describes the trend of sensor changes, while the standard deviation measures data variation relative to that mean. These four statistical features are calculated for each accelerometer axis (Ax, Ay, Az) and gyroscope axis (Gx, Gy, Gz), resulting in a total of 24 input features.

The extracted features are then used to train the Backpropagation Neural Network. The neural network architecture consists of one input layer, two hidden layers, and one output layer. The hidden layers process the extracted features, while the output layer generates binary or multi-class

classification results depending on the scenario. The architecture of the proposed BPNN model employed in this study is illustrated in Fig. 3. The input layer contains 24 neurons (i_1, i_2, …, i_{24}) corresponding to the extracted statistical features. The first and second hidden layers consist of 128 ($h_{1,1}$, $h_{1,2}$, …, $h_{1,128}$) and 64 ($h_{2,1}$, $h_{2,2}$, …, $h_{2,64}$) neurons, respectively, while the output layer consists of 8 neurons (o_1, o2, …, o_8) representing the eight observed activity classes.

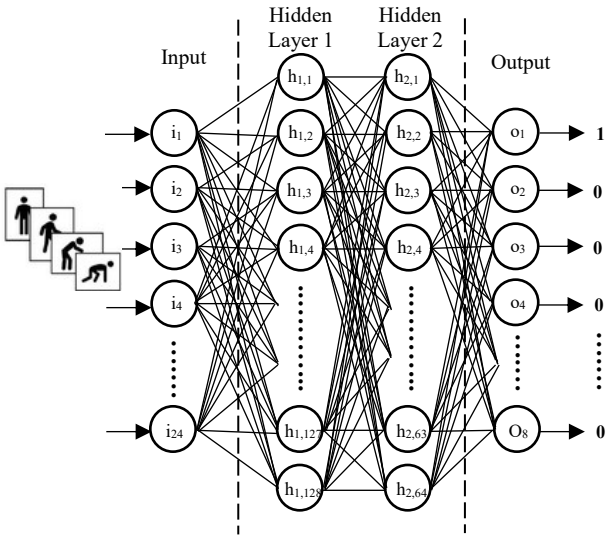

Fig. 3. Architecture of the backpropagation neural network employed in this study.

The input layer receives 24 statistical features derived from accelerometer and gyroscope data obtained during the pre-processing and feature selection stages. The output layer has 8 neurons representing eight activity classes: class 0 for standing to bowing, class 1 for standing to squatting, class 2 for sitting to standing, class 3 for standing to prostrating, class 4 for sitting to prostrating, class 5 for falling sideways, class 6 for falling forward, and class 7 for falling backward.

The proposed network incorporates two hidden layers because the accelerometer and gyroscope data exhibit complex non-linear characteristics. A narrowing structure (from 128 neurons to 64 neurons) was selected for this network to mimic the principle of gradual feature abstraction. The first hidden layer (128 neurons) serves to learn basic patterns and raw features from the input, while the second hidden layer (64 neurons) captures more complex relationships between features and distills that information into a more concise and meaningful representation, thereby enabling more optimal classification at the output layer [30]. Research in [31] indicates that the 128-64 neuron configuration achieves an optimal point (sweet spot) on the performance curve. This configuration yields high accuracy without showing signs of overfitting, thereby maintaining the model's flexibility when processing new data.

Both hidden layers use the ReLU activation function to handle non-linear decision boundaries. These functions satisfy the properties of continuity, differentiability, and monotonicity, which are essential for the learning process in artificial neural networks. It also accelerates the convergence during the network training process and prevents the vanishing gradient problem often encountered in artificial neural network models [32-33]. The ReLU (Rectified Linear Unit) activation function transforms negative input values into zero and passes positive values through directly, using Eq. (1).

$$ReLU(z) = max(0, z) \quad (1)$$

where, z is the neuron input value; if the input value is below zero ($z < 0$), the output is 0, and if the input value is greater than or equal to zero ($z \geqslant 0$), the output remains equal to the input value itself.

The output layer employs the Softmax activation function to transform the network channels into a probability distribution across the eight activity classes. Each probability value lies between 0 and 1, and the total sum of values at the output layer is always exactly 1 [34-35]. The Softmax function is defined in Eq. (2).

$$\hat{y}_i = \frac{e^{z_i}}{\sum_{j=1}^{n} e^{z_j}} \quad (2)$$

where, $\hat{y}_i$ is the probability of the ith class or the actual true label, z is output of the neuron before activation, e^{z_i} is the exponential function, n is the number of output classes, and $\sum_{j=1}^{n} e^{z_j}$ is the sum of all exponential values. The class with the highest probability value is the network prediction.

The training phase utilizes a training dataset and involves forward propagation, loss calculation, and bias and weight updates using the backpropagation algorithm. This process yields accuracy and loss metrics that indicate the quality of the training. The final weights and biases obtained from the training process are subsequently used to classify activities based on the testing dataset.

Forward propagation processes input data in a single forward direction through the layers of a neural network to generate a final prediction. Each neuron within a layer processes incoming values, x, using specific weights, w, and biases, b, transforms them via an activation function, and then passes the result, z, to the next layer, as shown in Eq. (3).

$$z = x \cdot w + b \quad (3)$$

After the forward propagation process generates a prediction at the output layer, the loss value is calculated to measure the magnitude of the difference between the network prediction and the actual ground-truth label. In our proposed BPNN architecture, the categorical cross-entropy loss function is used as it is suitable for multiclass classification problems, specifically the eight-class classification as discussed here. It measures the dissimilarity between the predicted probability distribution and the true one-hot encoded label distribution. The lower the resulting loss value, the better the model's ability to predict the correct class. The equation for the categorical cross-entropy loss function is shown in Eq. (4).

$$L = -\sum_i^n y_i \log(\hat{y}_i) \quad (4)$$

Once the loss value is obtained, the backpropagation process is performed to calculate the error gradients with respect to each weight and bias in the network. These gradients are used to iteratively update the network parameters so that the loss value decreases and the model's ability to classify activities improves.

Eq. (5) shows the weight update in the backpropagation algorithm using the network learning rate, denoted byη.

$$W_{new} = W_{old} - \eta \cdot \frac{dL}{dW} \quad (5)$$

A similar equation is also applied to the update in bias values.

D. Evaluation

The evaluation of the proposed fall detection system is conducted using a confusion matrix, which provides a detailed representation of classification results by distinguishing between correctly and incorrectly predicted classes. A multiclass confusion matrix for a neural network is an N × N grid (where N is the number of classes) that contrasts the network-predicted labels (columns) with the true target labels (rows). The diagonal cells display accurate predictions, while off-diagonal cells reveal particular misclassifications. The confusion matrix consists of four components: True Positives (TP), True Negatives (TN), False Positives (FP), and False Negatives (FN). These values enable the calculation of various performance metrics, including accuracy, precision, recall, and specificity, which are determined using the following equations.

$$Accuracy = \frac{TP+TN}{TP+FP+TN+FN} \quad (6)$$

$$Precision = \frac{TP}{TP+FP} \quad (7)$$

$$Recall = \frac{TP}{TP+FN} \quad (8)$$

$$Specificity = \frac{TN}{TN+FP} \quad (9)$$

Accuracy is the total correct predictions (sum of the diagonal) divided by the total samples; precision is true positives divided by all positive predictions, recall is true positives divided by the total actual positives; and specificity measures the proportion of actual negative cases correctly identified as negative by the neural network.

From the optimization perspective, the loss function guides network training, while these evaluation metrics evaluate real-world practical performance. In this study context, they provide a thorough review of an ANN-based fall detection system while guaranteeing classification accuracy and dependability.

III. Results and Discussion

This section presents the results of the proposed BPNN training process using the preprocessed training dataset, as well as the testing results using the test dataset. Afterward, the performance of the model is evaluated using metrics derived from the confusion matrix.

A. Model Training

A neural network learns patterns from data by modifying its internal biases and weights during training. The training process is evaluated based on changes in accuracy and loss values at each epoch to assess the model ability to learn movement patterns and its convergence rate. The variation in accuracy values throughout the training process is depicted in Fig. 4. At the beginning of the training, the accuracy level is low because the model was not yet able to optimally recognize data patterns. As the number of epochs increased, accuracy improved significantly, eventually reaching approximately 86% by the end of the training. The curve, which begins to flatten in subsequent epochs, indicates that the model has achieved convergence and is capable of effectively learning the characteristics of the training dataset of movement patterns.

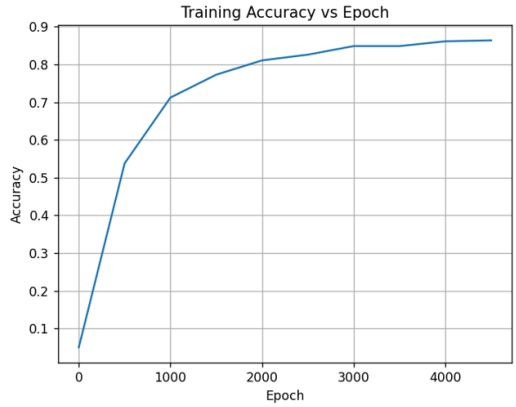

Fig. 4. Plot of accuracy vs epoch for training data.

The loss value indicates the magnitude of the prediction error produced by the model during the training process. The smaller the loss value, the better the model's ability to learn data patterns. Fig. 5 shows that the loss value decreases significantly at the beginning of the training process. As the number of epochs increases, the loss value continues to decrease until it reaches a relatively stable state. This decrease indicates that the optimization process has successfully minimized prediction errors and the model has reached a state of convergence.

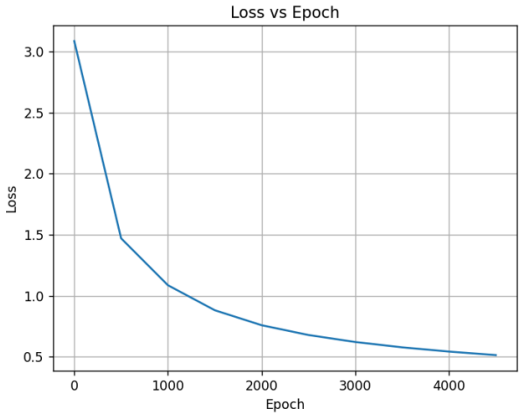

Fig. 5. Plot of loss vs epoch for training data.

B. Classification Performance

After the training process is completed, the proposed BPNN model is evaluated using test data to determine its ability to classify eight types of activities based on accelerometer and gyroscope sensor data. The evaluation is conducted using a confusion matrix, which provides information on the number of correct and incorrect predictions for each activity class. Based on this confusion matrix, the accuracy, precision, recall, and specificity are then calculated to measure the model's overall performance, as shown in Fig. 6.

Actual Data \ Prediction	Standing to Bowing (0)	Standing to Squatting (1)	Sitting to Standing (2)	Standing to Prostrating (3)	Sitting to Prostrating (4)	Falling Sideways (5)	Falling Forward (6)	Falling Backward (7)
Standing to Bowing (0)	7	0	0	0	0	0	0	0
Standing to Squatting (1)	1	6	0	0	0	0	0	0
Sitting to Standing (2)	0	0	7	0	0	0	0	0
Standing to Prostrating (3)	0	0	0	7	0	0	0	0
Sitting to Prostrating (4)	0	0	0	0	7	0	0	0
Falling Sideways (5)	0	0	0	0	0	6	0	1
Falling Forward (6)	0	0	0	2	0	0	5	0
Falling Backward (7)	0	0	0	0	0	0	0	7

Fig. 6. Confusion matrix of the BPNN to classify eight different movement patterns, including fall and non-fall.

The model is tested using 56 test data points consisting of seven participants across eight movement pattern classes. The test results show that 52 data points are classified correctly, while 4 data points are misclassified. These errors consisted of one sample of standing to squatting that is predicted as standing to bowing, two samples of falling forward that are predicted as standing to prostrating, and one sample of falling sideways that is predicted as falling backward. Test results revealed three movement patterns that were incorrectly predicted due to striking similarities among them; for instance, the transition from a standing to a squatting position closely resembles the movement from standing to bending over, while falling forward is similar to moving from standing to a prostrate position, and finally, falling sideways closely resembles falling backward. These classification errors indicate that some activities have similar patterns of acceleration and angular velocity changes, making it difficult for the model to distinguish between certain classes. Nevertheless, these results demonstrate that the model is capable of classifying the eight types of activities effectively.

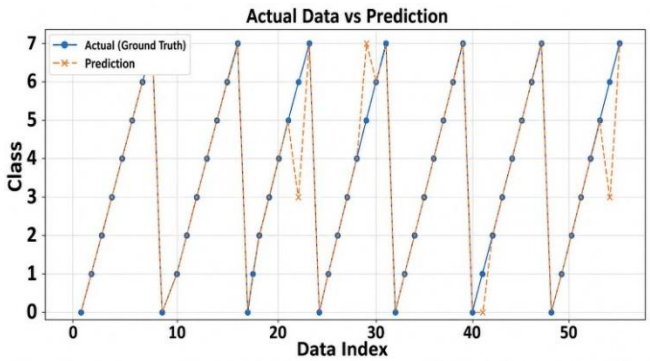

Fig. 7. Actual vs predicted class from all test data.

A comparison is made between the actual labels and the anticipated findings from all test data in order to produce a more comprehensible picture of the categorization results, as shown in Fig. 7. The model prediction results show all patterns nearly identical to the actual data. Most of the predicted points coincide with the actual data, indicating that the model is capable of accurately recognizing the patterns of the eight activity types. Differences are only visible at a few points representing the four samples that are misclassified, as explained in the confusion matrix results. This indicates that the model performs well in predicting activities based on accelerometer and gyroscope sensor data.

The classification results are then assessed using evaluation metrics, such as accuracy, precision, recall, and specificity, as described in Eq. (6)- (9), to obtain a quantitative estimate of the model performance. Based on the results of the confusion matrix, the model achieved an accuracy of 92.86%, indicating that the majority of the test data is classified correctly. Testing accuracy is higher than training accuracy; this is likely because the test data is smaller, cleaner, or inherently simpler compared to the training dataset. The test data comprises approximately 10% of the total dataset, whereas the training data accounts for 90%. In addition, the model achieved a precision of 94%, a recall of 85%, and a specificity of 97%. These values indicate that the model performs well in recognizing the eight types of activities and is able to accurately distinguish between falls and normal activities.

IV. Conclusion

This research successfully developed a comprehensive architecture and algorithm to detect fall and non-fall movement patterns using the backpropagation method within an artificial neural network. The designed system is capable of training on and predicting movement patterns based on data obtained from accelerometer and gyroscope sensors, thereby demonstrating its practical application in real-world scenarios.

Prior to the training process, the raw sensor data are preprocessed by calculating the difference (Δ) between consecutive samples and assigning activity labels to generate more representative input features. The dataset was collected from 69 participants, where data from 62 participants are used for model training and data from the remaining 7 participants are used for model testing. The training process achieved a training accuracy of 86.87% and a validation accuracy of 85.00%, indicating that the proposed model is able to learn the activity patterns effectively while maintaining good generalization performance. The proposed model is evaluated using a confusion matrix on the testing dataset. Experimental results showed that the model correctly classified 52 out of 56 activity samples, achieving an accuracy of 92.86%, precision of 94%, recall of 85%, and specificity of 97%. These findings demonstrate that the proposed backpropagation neural network, combined with the Δ-based preprocessing approach, is capable of accurately classifying eight human movement patterns and has the potential to be applied in inertial sensor-based fall detection system.

***Abstract*—Reactive jamming attacks are prevalent in low power Internet of Things networks and are severely affecting the performance of IoT nodes. Existing anti-jamming studies focus primarily on communication reliability. Limited attention has been given to the joint optimization of packet delivery ratio (PDR), energy consumption, and network lifetime in mobile IoT networks under reactive jamming attacks. This study proposes a double deep Q-network (DDQN)-based smart channel hopping model (SCHM) that improves communication reliability while reducing energy expenditure and extending network lifetime. We use a Markov Decision Process (MDP) for modelling the interaction between the jammer and the legitimate IoT node. We develop a DDQN-based SCHM algorithm using the Python programming language. We implement the DDQN-based SCHM approach in the NS-3.41 environment. We evaluated the effectiveness of DDQN-based SCHM against Deep-Q-Network (DQN)-based hopping, non-hopping, and random hopping approaches. The results showed that our proposed DDQN-based SCHM approach achieved an average PDR of 99%, experienced the lowest energy consumption, and prolonged the network lifetime of IoT nodes. The proposed DDQN-based SCHM approach improves communication reliability and energy efficiency of IoT nodes.**

***Keywords*—DDQN; SCHM; MDP; reactive jamming attacks; PDR; energy consumption; network lifetime**

I. Introduction

Various application domains such as smart homes, smart cities, and environmental monitoring are beneficiaries of IoT network systems and sensor systems. IEEE 802.15.4 specifically benefits from IoT network systems [1], [2], [3]. For example, IEEE 802.15.4 enables users with wearable devices and ingestible sensors to be monitored remotely [4]. This helps healthcare professionals remotely monitor patients with chronic diseases for better disease management. IEEE 802.15.4 IoT networks are vulnerable to various attacks, specifically reactive jamming attacks that affect their performance severely.

IoT networks are more susceptible to various cyber-attacks because they inherit common characteristics of wireless networks, namely: open access and shared access. Exposure to several malicious attacks originates from factors such as IoT nodes having minimal or no security features embedded in them [5].

This is because IoT nodes have energy constraints imposed on them and have limited computational capabilities. Therefore, the fact that IoT nodes utilize a shared transmission medium is also a concern [6].

During a reactive jamming attack, an attacker listens to activities in the channels and transmits high signal power to the active channel with the intention of disrupting communication [7]. A disrupted IoT node will try to retransmit the packets because of a lack of acknowledgment from the receiver. Rapid retransmission of packets can lead to a quick battery depletion of IoT nodes [8], [9]. This will further lead to a short lifetime of IoT nodes in the network. Furthermore, prolonged transmission delays and low PDR may be incurred. In IEEE 802.15.4 IoT networks, applications such as remote patient monitoring (RPM) with wearables or ingestible sensors will be left unmonitored due to jamming attacks, leading to poor chronic disease management [4].

Wireless sensor networks (WSNs) are applications of IoT networks and are susceptible to reactive jamming attacks. Sensor nodes are deployed in unattended areas and can be easily compromised. Reactive jamming attacks are frequently employed by attackers to disrupt normal operations of WSNs. The disruption of communication through jamming often leaves areas unmonitored in WSNs. The study by [10] suggested that jamming of communication channels can be mitigated by raising the transmission power of legitimate nodes. However, increasing power levels may lead to quick battery depletion of IoT nodes, leaving systems unmonitored [11].

This research proposes a DDQN-based SCHM approach, which is applied to mitigating reactive jamming attacks in IoT networks. This study uses the MDP for the formulation of jammer and legitimate node interaction. DDQN-based SCHM server, which runs independently, is used for training the learning agent. This research combines IoT networks, specifically 802.15.4, PDR, energy consumption, channel hopping, and reinforcement learning in one NS-3.41 framework. The performance metrics of our proposed system are: PDR, energy consumption, network lifetime, and packet loss. The NS-3.41 testbed that was used includes nine IoT nodes, the access point as the sink node, and one reactive jammer. The effectiveness of the proposed SCHM approach was validated against the DQN-based hopping approach, non-hopping approach, and random hopping approach. The obtained simulation results demonstrated that the proposed DDQN-based SCHM has increased PDR by an average of 6%, reduced energy consumption by IoT nodes by an average of 77.5%, prolonged

network lifetime of IoT nodes by an average of 27.3%, and reduced packet loss by an average of 88.5% compared to benchmark approaches.

The rest of the study is organized as follows: Section II presents analysis of related existing studies on reactive jamming mitigation, Section III presents the system model and problem formulation using MDP, Section IV presents the proposed DDQN-based SCHM approach, Section V presents the simulation setting and results, and Section VI presents the conclusion and future work.

II. Related Work

Recent advances in wireless communication security have focused on mitigating jamming attacks using intelligent channel selection strategies [12], [13], [14]. Traditional anti-jamming techniques, such as frequency hopping and spread spectrum, rely on predefined patterns and often fail in dynamic or adversarial environments [11], [15].

To address these limitations, reinforcement learning (RL) has been widely adopted for adaptive anti-jamming communication. Deep Q-Networks (DQN) have been used to enable agents to learn optimal channel selection policies without prior knowledge of jammer behavior [16]. For example, deep reinforcement learning-based hopping strategies have demonstrated improved robustness against stochastic and wideband jamming attacks.

However, standard DQN suffers from overestimation bias, which can degrade performance in highly dynamic environments [17]. To overcome this limitation, DDQN has been proposed, showing improved stability and convergence in anti-jamming scenarios [18]. These approaches enable more reliable decision-making under uncertain channel conditions.

In parallel, research in cognitive IoT networks has emphasized the importance of jointly optimizing communication reliability and energy efficiency. Reinforcement learning has been applied to balance throughput maximization with energy consumption minimization, particularly under adversarial interference such as jamming attacks [19].

Despite these advances, most existing studies rely on abstract simulation environments and do not fully capture realistic network behavior. In contrast, this work implements a DDQN-based smart channel hopping strategy within an NS-3 simulated IoT network under reactive jamming conditions. The proposed approach evaluates both PDR and energy consumption, providing a comprehensive assessment of communication performance and network sustainability under adversarial conditions.

The main contributions of this study are as follows:

- A realistic NS-3-based IoT simulation environment incorporating mobile sensor nodes, a fixed access point, and a reactive jammer operating in an IEEE 802.15.4 network.
- A DDQN-based smart channel hopping mechanism capable of selecting communication channels dynamically in response to jamming activity.
- A comprehensive performance evaluation framework that jointly measures packet delivery ratio, packet loss, energy consumption, and network lifetime.
- A comparative analysis of four communication strategies: non-hopping communication, random channel hopping, DQN-based channel hopping, and DDQN-based SCHM approach.
- An investigation of the trade-off between communication reliability and energy efficiency under reactive jamming conditions.

III. System Model and Problem Formulation

A. System Model

The simulation environment is implemented in NS-3.41, modeling an IoT network consisting of multiple mobile sensor nodes communicating with a fixed access point (AP). The IoT network consists of a set of transmission channels (C_1, C_2, …, C_n). A reactive jammer is introduced, which transmits interfering signals upon detecting legitimate communication. Each IoT node generates UDP traffic toward the AP using an IPv6 over 6LoWPAN stack. Node mobility is modelled using a random walk mobility model within a bounded area, while the jammer also follows a dynamic movement pattern. Fig. 1 shows the proposed system model for the IoT network.

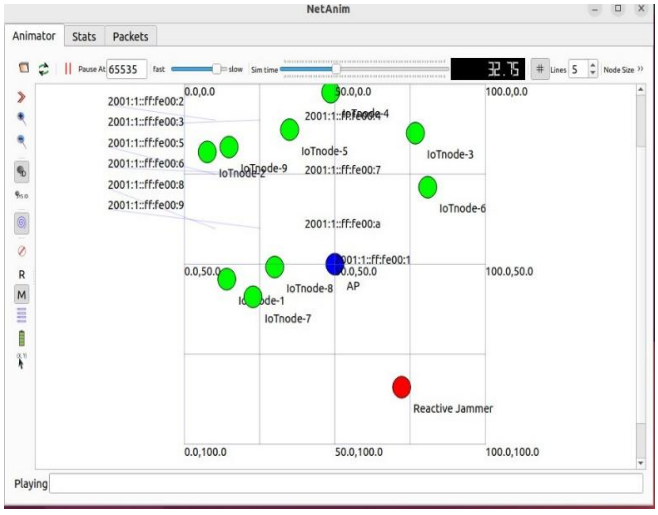

Fig. 1. System model for IoT network.

To mitigate reactive jamming effects, a DDQN-based SCHM agent is employed to perform smart channel hopping across available IEEE 802.15.4 channels. The agent observes the network state, including PDR, signal quality indicators, and energy consumption, and selects channel actions to maximize communication reliability and energy efficiency.

B. Jammer Model

The reactive jammer positions itself between the legitimate IoT node, sender (S), and the AP, receiver (R), and interrupts the communication by injecting a high-power signal. The actual transmitted signal by legitimate IoT nodes is affected by the normal noise known as Additive White Gaussian Noise (AWGN). Therefore, the optimal received signal at the

receiver's end without the presence of the jammer is given by Eq. (1):

$$R(t) = s(t) + g(t) \quad (1)$$

where, R(t) denotes the signal that is received, s(t) is the actual signal transmitted by the sender, and g(t) is the AWGN that can be between the path of the sender and the receiver.

The jammer can typically interrupt the communication by injecting the signal $s_j(t)$ into the active transmission channel. Therefore, the actual received signal at the receiver's end with the jammer in the vicinity is given by Eq. (2):

$$R(t) = s(t) + s_j(t) + g(t) + g_1(t) \quad (2)$$

where, $s_j(t)$ represents the actual jammer signal, and $g_1(t)$ is the AWGN between the jammer and the receiver. This research study uses Received Signal Strength (RSS) and PDR for detecting reactive jamming attacks. These parameters are estimated by most wireless communication systems that are equipped with transmitters and receivers.

C. Problem Formulation

Reinforcement learning requires the formulation of a Markov Decision Process (MDP). Therefore, the proposed SCHM approach adopts the MDP framework for the formulation of the optimization problem of the system. The MDP consists of the state space, action space, and the reward [20]. Typically, the agent observes the state space, which is the environment, and selects an action and eventually receives a reward accordingly.

1) State space: The IoT node is assumed to know nothing about the environment that it is interacting with, i.e., the status of the channel, the strategy of the jammer, the number of frames in the transmission queue, and the capacity of energy storage. The legitimate IoT node can only observe the chosen channel for communication. The state space is defined by Eq. (3).

$$S = \{(c, j, q, e): c \in (0,1), j \in (0,1), q \in (0, \dots, Q), e \in (0, \dots, E)\} \quad (3)$$

where, communication channel, $c = 0$, $c = 1$, denotes that the communication channel is idle and occupied, respectively. Jammer, $j = 0$ denotes that there is no attack on the communication channel and $j = 1$ that a jammer is attacking a communication channel. q denotes the packets in the transmission queue and e denotes the energy storage of the IoT node.

2) Action space: The IoT node can execute any of the following actions, namely, remain idle, actively transmit packets, or hop into another free radio channel and transmit packets when there is a jamming attack in the currently selected channel. The state space is defined by Eq. (4).

$$A = (a: a \in \{1,2,3\}) \quad (4)$$

where, 1 denotes that the IoT node remains idle, 2 denotes that the IoT node transmits packets, and 3 denotes that the IoT node hops into the unjammed communication channel.

3) Reward function: The immediate reward for the system is defined in this section. It is described as the number of packets that are sent to the receiver and positively acknowledged. The actions that the IoT node takes must reduce packet loss, which will increase PDR. Furthermore, the actions must reduce energy consumption, which will prolong the network lifetime of the IoT network. The reward function is defined in Eq. (5).

$$r(s, a) = \{pkt_{sen_{ack}}, hop_{suc}, avoid_{jam_{ch}}\} \quad (5)$$

where, $pkt_{sen_{ack}}$ denotes the packets that were sent and acknowledged successfully, hop_{suc} denotes that the learning agent hops successfully into an unjammed channel, and $avoid_{jam_{ch}}$ denotes that the learning agent avoids transmitting into the jammed channel.

IV. Proposed DDQN-Based SCHM Approach

A. Design of DDQN-Based SCHM

In this section, this research presents the development of a DQN algorithm for approximating the solution to the MDP problem formulated in Section III. The Q-learning algorithm, which is based on creating a reference table for selecting optimal actions and eventually storing state-action values in a table, cannot handle the jamming mitigation problem formulated in this research because the state space size is too large [21]. Consequently, this research study employs a DQN-based SCHM to fast-track the learning process and attain the best defence policy without being aware of the channel status and jamming strategy of the jammer.

This research adopts the Double-DQN method for approximating the Q-function. The reason is that DQN alone has a problem of performance instability due to a non-linear function [22]. DDQN utilizes two sets of neural networks, namely a policy network and a target network. DQN utilizes a target network to select and evaluate the next action. DDQN uses a policy network to select the next action and a target network to evaluate the action taken. Fig. 2 illustrates the proposed DDQN-based smart channel hopping strategy.

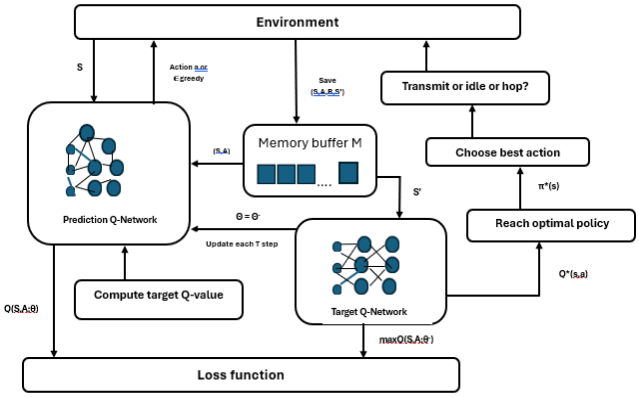

Fig. 2. Proposed DDQN-based SCHM approach.

To demonstrate the process, this research designs the DDQN-based smart channel hopping strategy shown in Algorithm 1. There are basically three significant elements of

the DDQN framework, namely the prediction Q-network $Q(s_t, a_t, \theta)$, the target Q-network $Q(s_t, a_t, \theta^-)$, and the memory buffer B.

The prediction network $Q(s_t, a_t, \theta)$ is used to approximate the Q-value; then the target Q-network $Q(s_t, a_t, \theta^-)$ and the memory buffer B are used to ensure that the DDQN is stable and that the target Q-value does not oscillate. The DDQN algorithm's advantage over the Q-learning algorithm is the ability to record the transition (s_t, a_t, r_t, s_{t+1}), i.e., the current state, the action, the immediate reward, and the next state observed by the legitimate node, in a memory buffer B and then train the Q-network every epoch time slot. During Q-network training, buffered transitions are sampled randomly from a memory buffer and are used to compute the corresponding target Q-value. Table I gives a summary of the symbols and their description.

Algorithm 1: DDQN-Based SCHM Algorithm

1. Initialization of prediction Q-network **Q** with random weight θ, target Q-network $\mathbf{Q}^-$ with random weight θ^- and the replay memory B with capacity M
2. for episode = 1,2, 3,..,E **do**
   Select two channels randomly from set C to initialize the state S, where N channels are used for communication and the other channel for hopping
3. for timeslot t = 1 to T **do**
   Choose a random action a_t with probability ∈, otherwise choose $a_t = \text{argmax}Q(s_t,a_t,\theta)$
4. Execute action a_t and receive the immediate reward r_t, then obtain next state s_{t+1}
5. Save transition (s_t, a_t, r_t, s_{t+1}) in replay memory B
6. Select random samples (s_i, a_i, r_i, s_{i+1}) from replay memory B
7. Calculate target Q-value using the Q-value function below
   $Y_j = r_j + \gamma Q(s_{j+1}, \text{argmax}_a Q(s_{j+1},a;\theta); \theta^-))$
8. The weights are then optimized by applying gradient descent using parameter θ to minimize the loss using the equation below
   $(y_j - Q(s_j,a_j; \theta))^2$
9. Repeat steps 6 to 8.
10. Replace $\mathbf{Q}^-$ with **Q** after a fixed number of steps
11. end for
12. end for

TABLE I. SYMBOLS AND THEIR DESCRIPTION

Symbol	Description
Q*(s, a)	Q-function given a state and action
Q_θ	Prediction network
Q_{θ^-}	Target network
t	timeslot
S	State space
A	Action space
s_t	State of the environment at timeslot t
a_t	Action taken at time slot t
r_t	Learning agent reward at time slot t
s_{t+1}	State of the environment at timeslot t+1
γ	Discount factor
∈	Epsilon

V. SIMULATION RESULTS

A. Simulation Setting

This research work implements an NS-3.41-based IoT simulation for evaluating reactive jamming and reinforcement-learning-based channel hopping. The simulation models mobile IoT nodes, a fixed access point, a reactive jammer, packet delivery ratio, packet loss, per-node energy consumption, and network lifetime. The reinforcement learning component is implemented separately in Python using a DDQN agent that selects channel-hopping actions based on network feedback from the NS-3.41 simulation. The plotting component is also separated into an independent Python script to compare non-hopping, random hopping, DQN-based hopping, and DDQN-based SCHM hopping scenarios. The contribution of this research is the integration of reactive jamming, channel hopping, DDQN decision-making, and performance evaluation into one experimental framework for studying communication reliability and energy efficiency in IoT networks under jamming attacks. RL parameters for simulation are shown in Table II.

TABLE II. RL PARAMETERS AND VALUES

Parameter	Value
Learning rate	1e-3
Gamma	0.98
buffer_size	20000
batch_size	64
target_update	100
Epsilon_start	1.0
Epsilon_min	0.05
Epsilon_decay	0.995

The performance metrics that were used in this research are energy consumption, PDR, network lifetime, and packet loss.

- Energy consumption – The amount of energy that the IoT node uses for transmitting or receiving packets. IoT nodes consume more energy during jamming attacks because of the need for retransmission when there is a lack of acknowledgment.
- PDR – Measures the number of packets that are successfully received at the destination in relation to the total packets sent at the source. Packet loss due to jamming attacks can significantly lead to poor PDR.
- Network lifetime – Refers to the duration of time in the LR-WPAN where all the nodes are active in the network during simulation and still have energy to participate in transmission of packets. This essentially measures the energy consumption of IoT nodes during the simulation.
- Packet loss – Occurs when data packets fail to reach the destination in the network. Interference caused by

reactive jamming attacks can result in severe packet loss in IoT networks.

B. Simulation Scenarios

Simulations are conducted under four scenarios, namely the non-hopping approach, which is a baseline, random hopping approach, DQN-based hopping approach, and DDQN-based SCHM approach, which is the proposed mitigation strategy.

- Non-channel hopping (baseline) where the IoT nodes use a single communication channel during transmission.
- Random channel hopping where the IoT nodes periodically switch the communication channels during transmission.
- DQN-based channel hopping, which uses a policy-based approach to send actions to the IoT nodes for switching to a new communication channel.
- DDQN-based SCHM approach where the learning agent receives network feedback from the network and selects actions and sends the signal to the IoT nodes for switching into the new communication channel.

The results are compared to assess the effectiveness of the proposed approach in improving network performance under reactive jamming conditions.

C. Results

When assessing the performance of four hopping strategies, the simulation period was configured in the NS-3.41 environment such that it runs for 220 seconds. Table III shows the simulation parameters and their values that were set on NS-3.41 environment during the simulation period.

TABLE III. SIMULATION PARAMETERS AND VALUES

Parameter	Value
BurstPackets	600
PacketSize	80 bytes
simulationTime	220 seconds
jamStartTime	20 seconds
jamEndTime	180 seconds
InitialEnergy	5.0 Joules
TransmitPowerW	60 Milliwatts
ReceivePowerW	50 Milliwatts
IdlePowerW	1 Milliwatts
FrequencyBand	2.4 GHz
NumOfChannels	16 (11 – 26)
JammerDetectionMetrics	RSS and PDR

To ensure methodological precision and improve the statistical reliability of the findings, each experimental scenario is repeated 20 times independently using the same simulation parameters. The results from these runs are aggregated by computing the mean PDR, while variation across runs is examined using appropriate dispersion measures such as standard deviation. Results are reported as mean ± standard deviation over 20 independent simulation runs, as shown in statistical summary Table IV. The mean PDR is recorded in percentage, mean packet loss is recorded in number of packets lost, mean energy is recorded as total energy consumed, and mean network lifetime is recorded in seconds relative to total simulation time.

TABLE IV. STATISTICAL SUMMARY

Scheme	PDR (%)	Packet Loss (number)	Energy (J)	Network Lifetime (s)
Non-hopping	89 ± 0.05	212 ± 1.89	8.5 ± 0	132 ± 0.72
Random hopping	93 ±1.28	134 ± 14.97	6.8 ± 1.39	172 ± 25.02
DQN	97 ± 1.25	5.4 ± 1.47	Mean ± SD	176 ± 26.12
DDQN	99 ± 0.57	9 ± 4.93	1.5 ± 0.47	220 ± 0

1) PDR: During the performance evaluation, the proposed SCHM approach, DQN hopping approach, random hopping approach, and non-hopping approach underwent mean PDR of 99%, 97%, 93%, and 89%, respectively, as displayed in Fig. 3. The proposed DDQN-based SCHM approach outperforms the DQN hopping approach by 2%. In addition, the proposed DDQN-based SCHM approach outperforms the random hopping approach by 6% PDR at the end of the simulation. Furthermore, the proposed DDQN-based SCHM approach outperforms the non-hopping approach by 10% PDR at the end of the simulation. The proposed approach significantly improves communication reliability as compared to non-hopping and random hopping approaches.

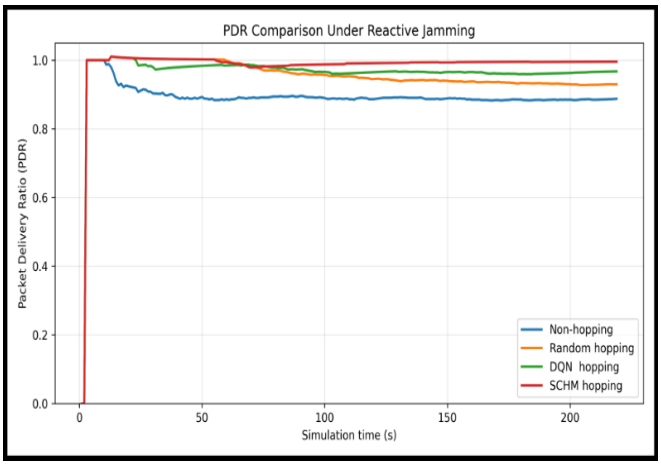

Fig. 3. PDR comparison under reactive jamming attack.

2) Energy consumption per node: All nodes, including the AP, are initially allocated the same energy budget of 5 Joules. During the performance evaluation, the average energy consumption per node for the proposed DDQN-based SCHM approach, DQN hopping approach, random hopping approach, and non-hopping approach is 1.5 Joules, 5.4 Joules, 6.8 Joules, and 8.5 Joules, respectively, as displayed in Fig. 4. Compared to the DQN hopping approach, the proposed DDQN-based

SCHM approach reduced energy consumption by 72.2%. Compared to the random hopping approach, the proposed SCHM approach reduced energy consumption by 77.9%. Compared to the non-hopping approach, the proposed DDQN-based SCHM approach reduced energy consumption by 82.3%. The proposed DDQN-based SCHM approach significantly improved the energy consumption of IoT nodes by the end of the simulation period. Random hopping and non-hopping strategies did not utilize energy efficiently, as shown in Fig. 4. All the nodes depleted the entire 5 joules of energy allocated to each of them at the end of the simulation.

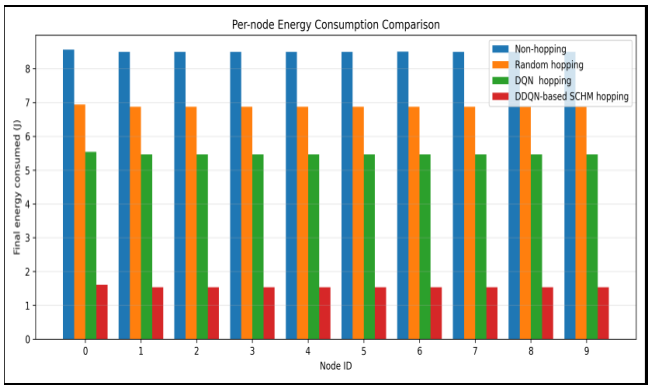

Fig. 4. Energy consumption comparison under reactive jamming attack.

3) Network lifetime: During the performance evaluation, the DQN hopping approach, random hopping approach, and non-hopping approach recorded the mean network lifetime of 176 seconds, 172 seconds, and 132 seconds of the simulation time, respectively. The proposed SCHM approach did not record any death of IoT nodes; all IoT nodes are alive by end of simulation period, hence the mean network lifetime recorded is 220 seconds. Compared to the DQN hopping approach, the proposed SCHM approach extended the network lifetime by 20% during the simulation period. Compared to the random hopping approach, the proposed SCHM approach extended the network lifetime by 21.8% during the simulation period. Compared to the non-hopping approach, the proposed SCHM approach extended the network lifetime by 40% during the simulation period. The proposed SCHM approach experienced the longest span in terms of network lifetime, as displayed in Fig. 5. DQN hopping, random hopping, and non-hopping strategies experienced short to medium durations of network lifetime. IoT nodes' energy is depleted before the simulation time expires, as shown in Fig. 5. The proposed SCHM approach extends network lifetime compared to DQN hopping, random hopping, and non-hopping approaches.

4) Packet loss: During the performance evaluation, the mean number of packet losses for the proposed DDQN-based SCHM approach, DQN hopping approach, random hopping approach, and non-hopping approach are 9 packets, 38 packets, 137 packets, and 212 packets, respectively, as demonstrated in Fig. 6. Compared to the DQN hopping approach, the proposed DDQN-based SCHM approach reduced packet loss by 76.3% during the simulation period. Compared to the random hopping approach, the proposed SCHM approach reduced packet loss by 93.4% during the simulation period. Compared to the non-hopping approach, the proposed DDQN-based SCHM approach reduced packet loss by 95.7% during the simulation period. The proposed DDQN-based SCHM approach experienced the lowest number of packet losses during the simulation, as shown in Fig. 6. The DQN hopping strategy experienced the lowest number of packet losses during the simulation. The random hopping strategy experienced a medium number of packet losses during the simulation. The non-hopping strategy experienced the highest number of packet losses, as displayed in Fig. 6.

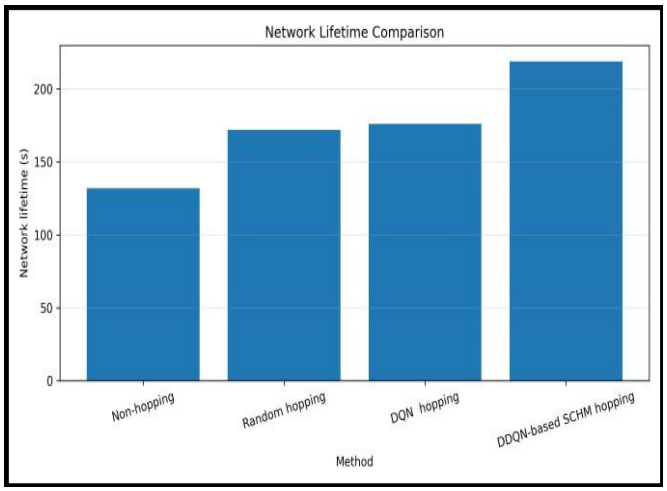

Fig. 5. Network lifetime comparison under reactive jamming attack.

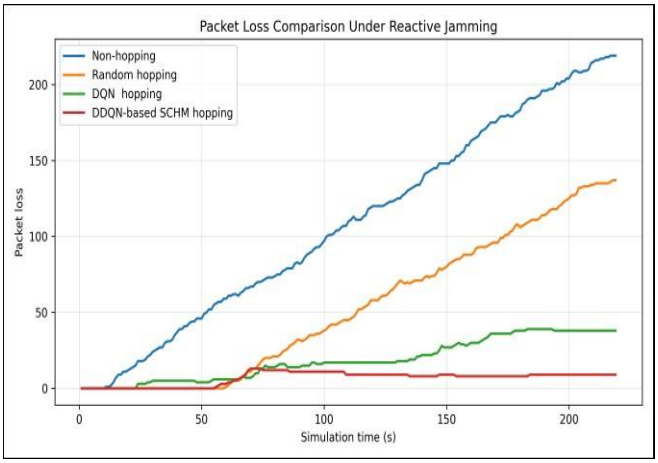

Fig. 6. Packet loss comparison under reactive jamming attack.

D. Discussion

The results demonstrate that the DDQN-based SCHM approach significantly improves communication reliability under reactive jamming conditions. Compared to the baseline scenario without channel hopping, the proposed approach achieves a higher PDR and reduces packet loss. This is shown in Fig. 3 and Fig. 6.

Furthermore, the DDQN-based SCHM agent exhibits improved energy efficiency by avoiding heavily jammed

channels, thereby reducing unnecessary retransmissions. This is shown in Fig. 4. This leads to a slower rate of energy depletion across IoT nodes and extends overall network lifetime. This is shown in Fig. 5.

When compared to random channel hopping, the DDQN-based SCHM approach shows more stable performance and faster adaptation to jammer behavior. These findings are consistent with existing literature, which highlights the advantages of deep reinforcement learning in dynamic and adversarial wireless environments.

This research study compares the proposed DDQN-based SCHM approach with the RL algorithm proposed by [16] and the DDQN algorithm proposed by [18]. The results of the study by [16] show that DRL-based hopping outperforms classical Q-learning and is robust even when jammer behaviour is unknown. The results of the study by [18] show that DDQN fixes overestimation problems, better stability and performance and DDQN performs better and more stable than DQN. The key validation factors are listed in Table V.

TABLE V. VALIDATION FACTORS

Metric	Paper [16]	Paper [18]	This research study
Throughput / PDR	Yes	Yes	Yes
Channel selection policy	RL-based	DDQN	DDQN
Jamming type	Probabilistic	Sweeping	Reactive
Performance improvement	DRL better than Q-learning	Fix overestimation	DDQN-based vs baseline
Limitations	Q-value overestimation	Did not evaluate energy or lifetime	Evaluates PDR, packet loss, energy, network lifetime and convergence

Overall, the proposed DDQN-based SCHM approach demonstrates the effectiveness of intelligent channel selection in enhancing both reliability and energy efficiency in IoT networks under jamming attacks.

VI. CONCLUSION

This research evaluated the performance of the proposed DDQN-based SCHM approach under reactive jamming attacks against DQN-based hopping, non-hopping, and random hopping approaches. The proposed DDQN-based SCHM approach was implemented using NS-3.41 with the IEEE 802.15.4 protocol, simulating an IoT network. The simulation results showed that the DDQN-based SCHM approach achieves better convergence in terms of reward, PDR, and loss. During the performance evaluation the following metrics were used namely: PDR, packet loss, energy consumption, and network lifetime. The simulation results demonstrated that the DDQN-based SCHM approach can improve PDR and reduce packet loss as compared to DQN-based hopping, non-hopping, and random hopping approaches. The simulation results showed that the proposed DDQN-based SCHM has improved communication reliability of the 802.25.4 IoT network. The results are consistent with similar studies that utilized DDQN.

Furthermore, the simulation results showed that the DDQN-based SCHM approach can significantly reduce energy consumption and prolong the network lifetime as compared to DQN-based hopping, non-hopping, and random hopping approaches. The simulation results showed that the proposed DDQN-based SCHM has addressed the shortcomings of the existing literature in similar studies. The existing literature has given little attention to energy consumption and network lifetime of IoT nodes and has focused on detection and communication reliability. As future work, the proposed DDQN-based SCHM approach can include performance improvements in QoS and channel access to reduce collisions. Future extension of the study will also evaluate the performance of the proposed approach in a scenario where multiple reactive jammers exist. In addition, future work can adopt the solution and evaluate it in multichannel jamming, UAV, and satellite navigation systems.

Comparative Evaluation of Synthetic Data Generation Methods for Binary Classification Problems with Class Imbalance

Jhonatan Esquivel, Christian Humpiri, Jose Vega, Nemias Saboya
Escuela Profesional de Ingeniería de Sistemas-Facultad de Ingeniería y Arquitectura,
Universidad Peruana Unión, Lima, Perú

***Abstract*—Class imbalance is a critical challenge in the classification of tabular data, since it affects the diagnostic capacity of models in domains such as health and finance. This research compares four synthetic data generation paradigms: traditional interpolation (SMOTE-NC), deep generative models (CTGAN and TVAE), and a hybrid scheme (SMOTE-NC-CTGAN) in which SMOTE-NC only densifies the minority data used to train the generator. Five UC Irvine datasets with imbalance ratios between 2.55:1 and 29.99:1 were used under a dual evaluation that combines multidimensional statistical fidelity (Wasserstein distance, correlation and categorical differences, and diversity) and predictive utility (AUC-PR, Recall, Precision, F1-Score, Specificity and G-mean), with a cost-sensitive baseline as reference. Each experiment was repeated in 10 runs that regenerate the synthetic data, and the differences were tested with paired tests, Holm correction, and effect sizes. SMOTE-NC obtains the highest fidelity in all datasets, while the CTGAN-based methods generate the most dispersed records under extreme scarcity. Synthesis does not improve the global ordering of predictions: of 40 comparisons, AUC-PR decreases significantly in 19 and increases only in 2, both in the most imbalanced dataset with XGBoost (HYBRID: 0.5252 versus 0.4872), an effect not observed with CatBoost. In contrast, Recall increases significantly in 27 of the 40 comparisons (e.g., from 0.1617 to 0.5835 with CTGAN in DS1), at the cost of Precision, and a class-weighted baseline produces a similar displacement. Data synthesis mainly shifts the decision boundary towards the minority class, which is favorable where false negatives dominate the cost.**

***Keywords*—Class imbalance; synthetic data; SMOTE-NC; CTGAN; hybrid models; machine learning; tabular classification**

I. Introduction

The imbalance of classes in datasets represents a very common challenge in machine learning tasks, as well as in the real world, where events of interest occur with low frequency. Consequently, classification algorithms often produce bias by favoring the majority class based on the level of imbalance. This problem has been addressed in various domains such as computer security, medical diagnosis, and detection of financial fraud, where incorrect detection can have critical consequences [1], [2], [3].

To address this problem, various approaches have been proposed, among which the oversampling of the minority class has been widely used. The methods derived from the Synthetic Minority Oversampling Technique (SMOTE) are effective and less computationally expensive with respect to other models. Likewise, they highlight how versatile they can be [2],[4]. However, these approaches have inherent limitations, since the generation of examples by means of linear interpolation can give rise to less diverse examples and does not adequately capture the complex relationships between variables.

Therefore, in recent years, different deep generative models have been created as a promising alternative for the generation of more realistic synthetic data [5]. In particular, Generative Adversarial Networks (GANs) have demonstrated a remarkable ability to learn complex data distributions and generate new samples that preserve the statistical characteristics of the original dataset [6]. These models have been applied in various domains and with different variations according to the context, such as CTGAN [7], CopulaGAN [8], CGAN [6], or AC-GAN [6].

Likewise, there are Variational Autoencoders (VAE), which seek to minimize the difference between the input and the reconstructed output, thus learning a compact representation of the data [8]. It presents multiple variants, and among them the most applied in the TVAE is a variation aligned to tabular data, which captures that, despite being highly sensitive to its hyperparameters, is a robust model whose performance varies according to the characteristics of the dataset [9]. However, the use of synthetic data introduces new challenges related to the quality and fidelity of the data generated, since some studies have indicated that the predictive capacity of models trained with synthetic data is not sufficient to evaluate their usefulness, as the statistical distributions and relationships between variables present in the original dataset must also be analyzed [10], [11].

More recently, some works have proposed hybrid approaches that combine traditional oversampling techniques with generative models. These strategies seek to take advantage of both approaches. On the one hand, the initial balancing facilitates the learning of the generative model. In contrast, the generative process allows the creation of more diverse and representative samples of the original distribution of the data [12], [13].

In this context, the present study aims to evaluate comparatively different synthetic data generation techniques for imbalanced binary classification problems. For this, traditional oversampling methods and generative models designed for tabular data are analyzed, including SMOTE-NC, CTGAN, and TVAE, as well as a hybrid SMOTE-NC-CTGAN approach. The

experiments are performed on multiple real datasets with unique characteristics, which allows evaluation of the behavior of these methods under different levels of imbalance.

The contributions of this work are: 1) a controlled comparison of interpolation, adversarial, variational, and hybrid generation under a common pipeline, with the same real records and classifiers; 2) a hybrid SMOTE-NC-CTGAN scheme for mixed-type data in which SMOTE-NC only densifies the minority data used to train the generator; 3) a dual evaluation of multidimensional fidelity and predictive utility, including a cost-sensitive baseline; and 4) a statistical validation over repeated runs that regenerate the synthetic data.

II. Literature Review

The problem of class imbalance has been widely studied since it is very relevant to machine learning models because this unequal distribution can produce bias or unjustified benefit towards the majority class, reducing its veracity. In the same way, recent literature has responded to this problem with various forms of oversampling, such as traditional techniques, generative models, variants, or hybrid approaches. This framework is responsible for precisely this: being able to compare and evaluate their fidelity against binary classification datasets with different levels of imbalance.

A. Class Imbalance in Tabular Data Sets

The literature agrees that class imbalance negatively affects models since many learn with a certain bias; consequently, they end up favoring the majority class. The study [2] summarizes that this problem is particularly critical in health, where the minority class usually corresponds to the most important clinical event. In a complementary way, the review [4] shows that both variants of SMOTE and approaches based on GAN have arisen precisely to correct this limitation in imbalanced classification tasks. Along the same lines, the work [3] points out that, in Android malware detection, the imbalance reduces the ability to generalize to the minority class. At the same time, [14] shows that even deep networks can remain biased if the training objective does not adequately control the unequal distribution between classes.

Therefore, generative models become relevant, and this is demonstrated in the study [15], where it is explicitly stated that imbalanced data sets hinder the development of robust models for predictions of obesity levels and that synthetic generation can efficiently support when samples or certain key variables are missing. However, the study [11] mentions that these methods must be analyzed quite carefully, because they can generate differences in distributions, correlations, or even privacy-related risks, especially when it is directly assumed that synthetic data will always be useful. In addition, in another context, the study [16] explains that in imbalanced regression problems, it is not enough to only increase the number of rare values, but it is also important to preserve the relationship between the variables and the continuous objectives. This shows that generating new data alone does not guarantee good results if the existing logic between the original data is not maintained.

B. Traditional Oversampling Techniques

Within traditional techniques, SMOTE continues to be one of the most used methods to treat the imbalance problem. Its operation is based on creating new samples of the minority class through interpolation between close neighbors, simply avoiding copying existing instances. The work [17], applied to the area of phishing detection, demonstrates that the combination of SMOTE-NC together with XGBoost achieved 98.0% accuracy and 98.5% recall, surpassing the model trained without re-sampling. This shows that data balancing can significantly improve the ability to detect the minority class.

Similarly, the study [18] concludes that the combination of SVM + SMOTE-NC presents better results compared to SVM without balancing techniques, especially in data sets containing nominal and continuous variables. In these cases, improvements in both accuracy and F1-score were observed. On the other hand, some applied works also support the usefulness of these techniques. In the case of credit card fraud detection, [1] reports a fairly extreme scenario where fraud only accounts for 0.172% of transactions made. In that study, the combination of Random Oversampling with XGBoost obtained the best performance, reaching an F1-score of 92.43%, accuracy of 97.383%, and recall of 88.418%. Likewise, the study [19] shows that after applying SMOTE to correct an imbalance ratio of 60:40 in zygosity prediction, XGBoost was again positioned as the model with the best results, achieving 85.57% accuracy and 86.72% F1-score.

In general, the studies analyzed suggest that traditional oversampling techniques still maintain a fairly competitive performance, especially when combined with robust classifiers. In addition, they allow for improving the detection of the minority class without increasing the complexity of the pipeline too much. However, studies [4] and [16] also point out that these methods can generate overly generalized or unrealistic samples when the feature space has complex structures. Due to this, their ability to represent heterogeneous tabular distributions may be limited in some scenarios.

C. Generative Models for Tabular Data

The advancement of generative models has opened the possibility of going beyond SMOTE's own local interpolation. The review [6] highlights that GANs have gained relevance as tools to alleviate imbalance in tabular datasets when modeling complex distributions. In this line, CTGAN has become one of the most used models because it was designed to work with mixed and imbalanced tabular data. The study [10] evaluated CTGAN using the Cleveland heart disease dataset and found that the model manages to reproduce the general distribution and some important correlations, especially in variables such as age, thalach, and oldpeak. However, there are still differences in certain categorical attributes. In addition, [10] mentions that the predictive usefulness of synthetic data is moderate, since although the data generated captures relevant patterns, they fail to replicate the original labels fully.

Similarly, the work [20] compared CTGAN and TVAE in tabular datasets of different sizes and concluded that both models can retain statistical properties. However, their performance depends quite a bit on the size of the data and the configuration used during training. On the other hand, [21] presents an improved conditional GAN architecture for cardiovascular data and reports a mean KS of 0.3900, close to TVAE (0.3858) and higher than CTGAN (0.4803). This shows that the behavior of generative models can vary depending on the characteristic evaluated. In fact, the study points out that some variables are better represented by TVAE and others by the proposed model, so there is no single dominant model. This idea coincides with [11], where TVAE is described as a fairly robust and stable method even in complex datasets with many categorical variables. However, it is also mentioned that it may present greater privacy risks, as some synthetic data tends to look too much like actual records.

D. Hybrid Approaches to Synthetic Generation

On the other hand, a particularly relevant line for this research is that of hybrid methods, which try to combine the simplicity of classic oversampling with the ability of generative models to learn more complex distributions. Article [12] is central at this point, since it proposes SMOTified-GAN, where the samples generated by SMOTE replace random noise as input to the GAN. The work [12] reports that this approach improved the F1-score by up to 9% with respect to the next-best method and that it surpassed the other algorithms in 10 out of 11 datasets, showing especially clear advantages in sets with very small minority classes.

Subsequent evidence goes in the same direction. The study [22] focused on financial fraud and compared SMOTE, GAN, SMOTified-GAN, SMOTE+GAN, and GANified-SMOTE, concluding that hybrid approaches are more consistent than individual methods and that performance also depends on the proportion of synthetic samples generated. In turn, [23] compares traditional oversampling techniques with CGAN and CTGAN in medical data with imbalance ratios of 6.8, 9, and 19, finding that GAN-BASED variants achieve better performance than several classic techniques in terms of AUC and F1-score. Finally, [24] shows that even the proportion between synthetic samples from SMOTE and GAN can be optimized by genetic algorithms, which indicates that the success of hybrids does not depend only on the generative model but also on the balance between diversity, realism, and the number of artificial samples. This line of evidence methodologically supports the SMOTE-NC-CTGAN approach evaluated in this study, which is inspired by [12] but differs from it in three aspects.

First, SMOTified-GAN replaces the random noise of the generator with SMOTE samples, whereas here SMOTE-NC only expands the minority class up to 50% of the majority class, and CTGAN is then trained on this expanded set. Second, the interpolated records are discarded afterwards, so the final set contains only real and CTGAN records. Third, SMOTE-NC and the conditional generator of CTGAN [37] handle mixed numerical and categorical variables natively, whereas [12] and [22] used standard GANs on mainly continuous features.

E. Classification Models in Imbalanced Contexts

In addition to the generation method, the literature shows that the final performance depends on the classifier used. The article [1] shows that, in credit card fraud, ensemble and boosting models especially benefit from balancing, and that XGBoost can outperform other classifiers when combined with appropriate oversampling techniques. Similarly, [19] reports that XGBoost, Logistic Regression, and Gradient Boosting had comparable behaviors in zygosity prediction, although XGBoost was ultimately selected for its slight advantage and better subsequent interpretability by SHAP. In cybersecurity, [17] also shows that XGBoost combined with re-sampling techniques achieves a very high balance between sensitivity and specificity, supporting its choice in imbalanced tabular classification contexts.

On the other hand, [25] demonstrates that balancing can also enhance explainable ensemble models in cardiovascular prediction, while [1] and [17] reinforce the idea that tree-based and boosting models are usually more robust than simple linear alternatives when the dataset is heterogeneous or highly imbalanced. Taken together, this evidence justifies the use of XGBoost and CatBoost as the main classifiers in the experimental phase of this study, leaving Logistic Regression as an auxiliary tool for the selection of hyperparameters during synthetic generation.

F. Metrics to Evaluate and Verify Synthetic Data

An important aspect of recent research is that the evaluation of synthetic data should not focus only on the final performance of the classifier. The study [26] explains that, in imbalanced problems, metrics such as precision, recall, and F1-score are usually more useful than accuracy to analyze behavior about the minority class. In addition, mentions that the metric used should depend on the objective of each problem.

Similarly, the work [8] compares CTGAN, CopulaGAN, VAE, and SMOTE in anonymous traffic classification. It points out that it is not enough to only measure predictive performance, but it is also necessary to evaluate the quality of the data generated. In that study, SMOTE managed to increase the F1-score values by about 7.5% compared to the control group, while LightGBM reached an F1-score of 90.3% over eight types of applications. This shows that the final performance changes depending on the generative method and the classifier used subsequently.

In addition, the study [10] mentions that the evaluation should include other aspects such as numerical and categorical fidelity, the preservation of correlations, and the similarity between real and synthetic data. On the other hand, [27] reports that AE-CTGAN obtained better results than an autoencoder combined with a conventional GAN, reaching an average accuracy of 0.9929 for BMR in bladder cancer and 0.9748 for menopausal status in breast cancer. It also significantly decreased the distance between real and synthetic samples.

Finally, [28] demonstrates that synthetic data can also improve generalizability in medical vision tasks. Through the use of conditional StyleGAN, the mAP increased from 0.86 to 0.93, while the recall in flat or depressed lesions increased from 0.72 to 0.87. These results suggest that the evaluation of synthetic data should not focus only on statistical fidelity but also on the real utility and generalization capacity they bring to the model.

G. Research Gap

Despite the advances made in the treatment of class imbalance, there are still some important limitations within the current literature that this study seeks to address:

1) Homogeneity of the approaches compared: Many investigations tend to compare methods belonging to the same family of algorithms, such as variants of SMOTE or different GAN architectures. This makes it more difficult to analyze how different generative approaches respond to the same scenario.

2) Lack of a dual evaluation: There are still few studies that jointly analyze the statistical fidelity of synthetic data and its predictive utility, although both dimensions do not always exhibit the same behavior.

3) Little evidence in extreme scenarios: There is still little evidence on the performance of these techniques when the imbalance exceeds critical ratios greater than 20:1, a context where several interpolation methods tend to lose effectiveness.

In this context, the present research seeks to cover these limitations through a direct comparison between four different approaches: SMOTE-NC as a traditional interpolation method, CTGAN based on deep adversarial learning, TVAE through variational modeling, and a hybrid proposal called SMOTE-NC-CTGAN. In this way, the behavior of these models is evaluated using health and finance datasets, especially in scenarios with high levels of data scarcity.

III. Methodology

This research follows a quasi-experimental and empirical experimental design, developed through a six-stage pipeline. The objective is to evaluate how generative techniques influence the performance of gradient boosting classifiers (Fig. 1).

A. Datasets Presentation

For the study, five datasets from the UC Irvine Machine Learning Repository [29] were used, selected to present different levels of class imbalance and different degrees of complexity. The sets mainly belong to the areas of health and finance, in addition to containing numerical and categorical variables. Likewise, the imbalance ratios range from moderate scenarios to extreme cases close to 29.99:1, allowing the behavior of the techniques to be analyzed under different conditions.

It is important to note that, although all data sets were obtained through the UCI repository, there are differences in their provenance. Datasets 2, 4, and 5 correspond to sets directly integrated into the repository, while datasets 1 and 3 are curated versions of external sources. In particular, dataset 1 originally came from the Behavioral Risk Factor Surveillance System of the Centers for Disease Control and Prevention (CDC), and dataset 3 from ClinicalTrials.gov, both of which were later structured and adapted by UCI for use in machine learning tasks.

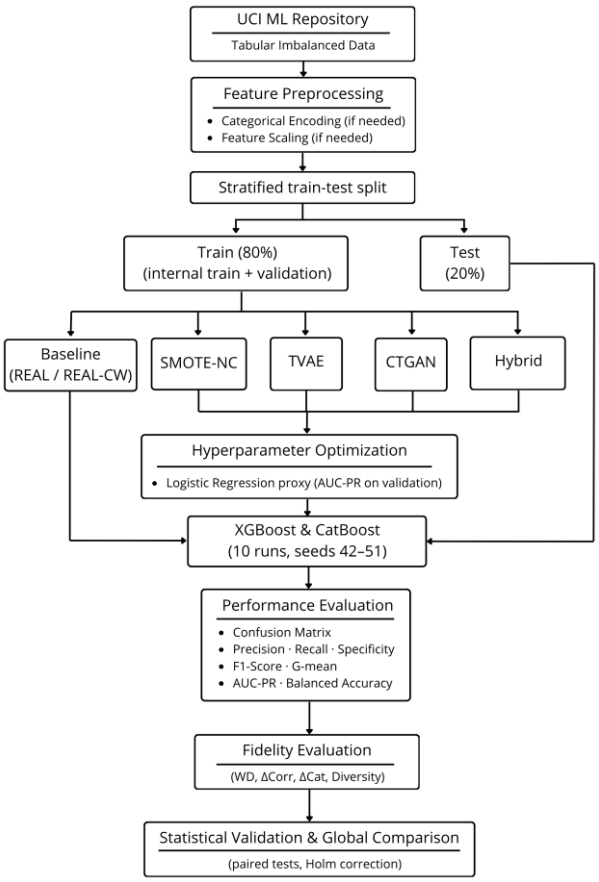

Fig. 1. Methodological flow.

TABLE I. Dataset Distribution Table

Dataset	Name	Domain	Samples	Features	Numerical	Categorical	Ratio	Minority n (%)	Ref.
DS1	Diabetes Health Indicators	Healthcare	253,680	21	5	16	6.18	35,346 (13.9%)	[30], [31]
DS2	Thyroid Cancer Recurrence	Healthcare	383	16	1	15	2.55	108 (28.2%)	[32]
DS3	AIDS Clinical Trial (175)	Healthcare	2,139	23	9	14	3.1	521 (24.4%)	[33], [34]
DS4	Credit Card Default	Finance	30,000	23	14	9	3.5	6,636 (22.1%)	[35]
DS5	Taiwanese Bankruptcy	Finance	6,819	95	93	2	29.99	220 (3.2%)	[36]

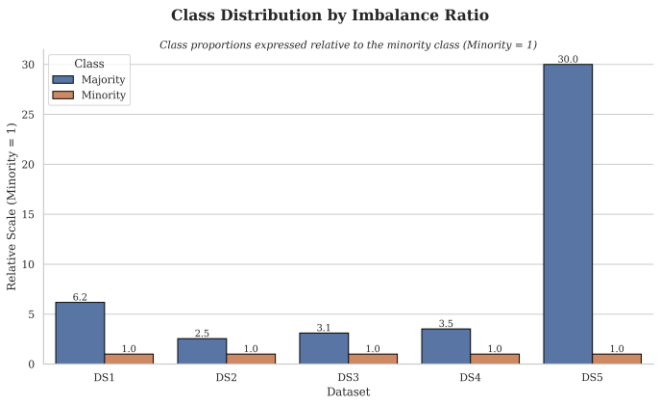

Fig. 2. Distribution of classes by dataset.

It should be noted that the DS5 (Taiwanese Bankruptcy) constitutes the "stress case" of this research, due to its extreme imbalance ratio and its high dimensionality (95 features), factors that impose a critical challenge to the generalizability of generative models.

Imbalance ratio and dataset size are not independent in this benchmark: DS2 and DS5 have the smallest minority classes (Fig. 2). Table I therefore reports the size of the minority class, which is considered in the interpretation (Section V).

B. Data Pre-Processing

Although the datasets come from consolidated sources, a standardized transformation protocol was applied to ensure convergence of the generative models. Both transformations were fitted exclusively on the training partition and then applied, without refitting, to the test partition:

1) Categorical coding: Label Encoding was used to transform nominal variables into integer representations, guaranteeing compatibility with the *Gumbel-Softmax* activations of the CTGAN and TVAE architectures.

2) Numerical standardization: Continuous variables were normalized using StandardScaler, as this facilitates the learning process in neural networks and improves the behavior of distance-based methods, such as SMOTE-NC. CTGAN and TVAE were trained on the variables in their original scale, since they apply their own mode-specific normalization [37]; their outputs were then transformed with the same scaler before being used by the classifiers.

C. Data Division

Each dataset was divided into 80% for training and 20% for testing by stratified sampling (seed 42). The test partition was isolated before any transformation and used only once, for the final evaluation, which prevents data leakage. The training partition was further divided (80/20, stratified) into an internal training subset, the only real data used by the generators and by all classifiers, including the baseline, and a validation subset used only for hyperparameter selection.

D. Generation of Synthetic Data

Four strategies representing different approaches to treating class imbalance were used in this research: a traditional technique (SMOTE-NC), two modern generative models (CTGAN and TVAE [37]), and a hybrid proposal called SMOTE-NC-CTGAN. This allowed us to compare methods with different ways of generating synthetic data.

For all methods, only the minority class of the internal training subset was used as the source, and $M - m$ records were generated to reach a 1:1 ratio (M and m: majority and minority sizes). SMOTE-NC interpolates numerical variables between minority neighbours and assigns the most frequent category among them; CTGAN and TVAE were trained only on minority records. The hybrid approach follows Algorithm 1.

Algorithm 1. SMOTE-NC-CTGAN hybrid generation

Input: internal training subset (X, y) with M majority and m minority records; densification floor $\alpha = 0.5$; k selected for SMOTE-NC; CTGAN hyperparameters θ; scaler S fitted on the training partition.

1: Apply SMOTE-NC with k to the scaled data until the minority class reaches $\lceil \alpha \cdot M \rceil$ records (real and interpolated).

2: Map the expanded minority set back to the original scale with S^{-1}.

3: Train CTGAN(θ) exclusively on the expanded minority set, declaring the categorical variables as discrete columns.

4: Sample $M - m$ synthetic records from the trained CTGAN.

5: Discard the interpolated SMOTE-NC records; the final set is formed by the original real records and the $M - m$ CTGAN records (1:1 ratio).

6: Scale the numerical variables with S before training the classifiers.

Output: balanced training set.

The floor $\alpha = 0.5$ gives CTGAN a larger minority sample while limiting the share of interpolated records; it was fixed a priori and not tuned.

The hyperparameters of the generators were selected per dataset by grid search on the internal train/validation split: $k \in \{3, 5, 7\}$ for SMOTE-NC; (epochs, batch size) $\in \{(300, 500), (500, 500), (500, 1000)\}$ with pac = 10 for CTGAN and the CTGAN stage of the hybrid; and (epochs, batch size, embedding dimension) $\in \{(300, 256, 128), (500, 256, 128), (500, 512, 256)\}$ for TVAE. Each candidate was scored by the AUC-PR on the validation subset of a Logistic Regression proxy, chosen for its low cost and its sensitivity to the training distribution; the selected values are listed in Table VI (Appendix).

E. Classifier Models

Once the balanced datasets were generated, the XGBoost and CatBoost classifiers were trained with a fixed configuration (300 trees, learning rate 0.05, depth 6, log-loss; XGBoost also with 0.8 row and column subsampling) and the default threshold of 0.5, without tuning, so that the differences can be attributed to the training data. Two references were trained on the same real data: REAL, without treatment, and REAL-CW, which weights the minority class by the imbalance ratio (cost-sensitive baseline).

Each experiment was repeated in 10 runs (seeds 42 to 51); each run regenerates all synthetic data and retrains the classifiers, while the train/test partition is fixed. The results are presented as averages accompanied by their Standard Deviation.

F. Fidelity Evaluation and Evaluation Metrics

For this research, an evaluation divided into two parts was proposed, since it is not only important that the synthetic data resemble the originals, but also to check if they really help the performance of the models. In the statistical fidelity part, the Wasserstein Distance was mainly used because it allows comparison of how similar the distributions of the real data are to the synthetic ones. In addition, this metric is based on the theory of optimal transport, so it helps to observe whether the generator model manages to preserve the original structure of the data even when there is high dimensionality.

Likewise, the analysis also considers the Correlation Difference and the Categorical Difference because both help to verify whether the relationships between variables and the proportions of the categories remain similar with respect to the original dataset. Likewise, the Diversity Score allows evaluation of whether the model is capable of generating varied data and not simply repeating very similar records. It is compared with the diversity of the real minority records: values far above it indicate records dispersed beyond the real data.

On the other hand, to measure predictive utility, the Area Under the Precision-Recall Curve (AUC-PR) was taken as the main metric, mainly because it offers a better analysis in scenarios where there is a severe imbalance of classes: its baseline equals the prevalence of the minority class, and it does not depend on a threshold [38]. In addition, this analysis was complemented by Precision and F1-Score, since they allow observing the balance between correctly detecting the minority class and avoiding unnecessary false alarms.

Recall was also considered because it allows us to measure more directly how many cases of the minority class are recovered correctly by the model, and Specificity and the G-mean [39] were added to quantify the cost on the majority class. Meanwhile, the Balanced Accuracy helps maintain a more balanced assessment considering the performance of both classes. Finally, the confusion matrices allowed these results to be interpreted in a more practical way.

Additionally, a hypothesis testing protocol was incorporated to determine if the differences observed between the methods are attributable to the synthesis procedure or to random variability between runs. Since all conditions share runs, seeds, and test partition, the design is paired. For each family of four comparisons (synthetic methods versus REAL, same dataset, classifier and metric), p-values were corrected with Holm-Bonferroni, and the effect size (d_z) and the 95% confidence interval are reported; REAL-CW is tested separately.

Normality of the paired differences was checked with Shapiro-Wilk; when it was rejected ($p<0.05$), which is frequent for Recall or Precision in small test sets, the Wilcoxon signed-rank test was used instead of the t-test. Independence holds at the level of runs, although all runs share the same test partition, so the inference refers to the variability of the procedure. Non-significant results indicate insufficient evidence, not absence of effect.

Finally, all comparisons keep the classifier constant; Table III and the figures show CatBoost, and Table VII (Appendix) shows XGBoost.

IV. Results

Below are the main findings obtained after executing the experimental pipeline:

A. Statistical Fidelity Analysis (Quality Metrics)

In this first stage, the ability of generative models to replicate the distribution of the minority class is evaluated. This phase is important because if the synthetic data does not maintain adequate statistical fidelity, the classifier could lose the ability to correctly generalize to real data.

The results are presented in Table II, where the performance of the four paradigms is compared using different quality metrics. Among them is the Wasserstein Distance (WD), used to measure the similarity between real and synthetic data. In addition, the Correlation Difference (Corr) and the Categorical Difference (CAT) were used to verify whether the relationships between variables and the categorical proportions are adequately preserved. Finally, the Diversity Score (DIV) allowed evaluation of whether the model generates varied samples and avoids producing repetitive data that may affect learning.

The analysis of Table II shows different behaviors according to the characteristics of each dataset:

Domain of interpolation in all scenarios: SMOTE-NC obtains the lowest Wasserstein distance in the five datasets. In DS1 (Diabetes Health Indicators), with a ratio of 6.18:1, it reaches 0.0429 ± 0.0005, compared with 0.1652 for CTGAN and 0.1471 for TVAE, which indicates that interpolation preserves the statistical structure well when there is a sufficient amount of real data.

Response in categorical datasets: An interesting case appears in the DS2 (Thyroid Cancer). Although it has the lowest ratio (2.55:1), the presence of many categorical variables represents a difficulty for several traditional methods. In this scenario, HYBRID achieves a better adaptation to the nominal proportions, reaching the smallest Categorical Difference (0.1269 ± 0.0279), thus surpassing SMOTE-NC (0.2887) and TVAE (0.3208).

Greater diversity in extreme scenarios: In the DS5, with a ratio of 29.99:1, there is a more marked difference between fidelity and diversity. SMOTE-NC keeps a low WD (0.0913) and a diversity (9.24) close to that of the real records (12.11), whereas CTGAN and HYBRID reach 42.55 and 46.20, together with the highest WD of the study (1.1981 and 1.0716). This diversity mostly reflects records dispersed outside the real minority class, consistent with the only 141 minority records available in 95 dimensions.

To complement this analysis, Fig. 3 shows the evaluation of fidelity and diversity corresponding to the base scenario DS1.

TABLE II. GLOBAL SUMMARY OF STATISTICAL FIDELITY METRICS (MEAN ± SD OVER 10 RUNS)

Dataset	Ratio	Method	WD (↓)	ΔCorr* (↓)	ΔCat (↓)	Div. (≈ real)
DS1	6.18	SMOTE-NC	0.0429 (± 0.0005)	0.0087 (± 0.0008)	0.0548 (± 0.0006)	2.8363 (± 0.0277)
		CTGAN	0.1652 (± 0.0449)	0.0726 (± 0.0265)	0.1453 (± 0.0178)	3.0061 (± 0.2121)
		TVAE	0.1471 (± 0.0370)	0.0635 (± 0.0114)	0.1168 (± 0.0168)	2.4460 (± 0.1620)
		HYBRID	0.1449 (± 0.0309)	0.0635 (± 0.0184)	0.1265 (± 0.0344)	2.8552 (± 0.1382)
		Real minority	—	—	—	2.8756
DS2	2.55	SMOTE-NC	0.1278 (± 0.0476)	-	0.2887 (± 0.0250)	1.0809 (± 0.0565)
		CTGAN	0.5730 (± 0.1989)	-	0.1982 (± 0.0576)	1.7503 (± 0.1011)
		TVAE	0.1347 (± 0.0422)	-	0.3208 (± 0.0317)	1.0814 (± 0.0358)
		HYBRID	0.7813 (± 0.2234)	-	0.1269 (± 0.0279)	1.2114 (± 0.1222)
		Real minority	—	—	—	1.1628
DS3	3.10	SMOTE-NC	0.0958 (± 0.0077)	0.0355 (± 0.0028)	0.1659 (± 0.0080)	3.5990 (± 0.0348)
		CTGAN	0.6533 (± 0.0976)	0.1335 (± 0.0100)	0.1195 (± 0.0146)	5.0332 (± 0.2063)
		TVAE	0.2305 (± 0.0232)	0.0751 (± 0.0069)	0.2188 (± 0.0199)	3.4832 (± 0.0438)
		HYBRID	0.5045 (± 0.0975)	0.1311 (± 0.0125)	0.1273 (± 0.0109)	4.9659 (± 0.2123)
		Real minority	—	—	—	4.0682
DS4	3.52	SMOTE-NC	0.0281 (± 0.0035)	0.0170 (± 0.0027)	0.0621 (± 0.0028)	3.6468 (± 0.1274)
		CTGAN	0.1358 (± 0.0132)	0.1981 (± 0.0079)	0.3000 (± 0.0282)	4.4143 (± 0.1854)
		TVAE	0.0901 (± 0.0083)	0.0701 (± 0.0024)	0.1052 (± 0.0256)	3.5753 (± 0.1314)
		HYBRID	0.1159 (± 0.0138)	0.0909 (± 0.0059)	0.2758 (± 0.0401)	3.8830 (± 0.1048)
		Real minority	—	—	—	3.8432
DS5	29.99	SMOTE-NC	0.0913 (± 0.0021)	0.0303 (± 0.0015)	0.0146 (± 0.0011)	9.2412 (± 0.1190)
		CTGAN	1.1981 (± 0.0699)	0.1523 (± 0.0004)	0.0937 (± 0.0032)	42.5466 (± 1.4128)
		TVAE	0.2637 (± 0.0037)	0.1177 (± 0.0023)	0.0213 (± 0.0001)	5.4916 (± 0.1263)
		HYBRID	1.0716 (± 0.0569)	0.1482 (± 0.0058)	0.1144 (± 0.0110)	46.2043 (± 1.0787)
		Real minority	—	—	—	12.1129

(↓) indicates lower values are better; (≈ real) indicates that values closest to the diversity of the real minority records are preferable.

WD: Wasserstein Distance; ΔCorr: Correlation Difference; ΔCat: Categorical Difference; Div: Mean Pairwise Distance; Real minority: diversity of the real minority records of the internal training subset, used as reference.

*Note: ΔCorr is not applicable (-) for DS2 because it contains only one numerical feature (Table I), making pairwise correlation uncalculable.

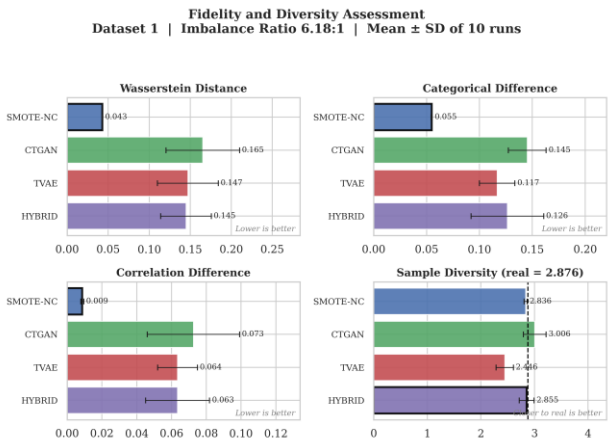

Fig. 3. Dataset fidelity and diversity evaluation 1.

Fig. 3 shows that in the Correlation Difference panel all methods stay at low values, with SMOTE-NC presenting the lowest error and an almost zero variance between runs. The Sample Diversity panel includes the diversity of the real minority records as a reference: in DS1, SMOTE-NC and HYBRID remain closest to it, CTGAN slightly exceeds it, and TVAE generates less varied records.

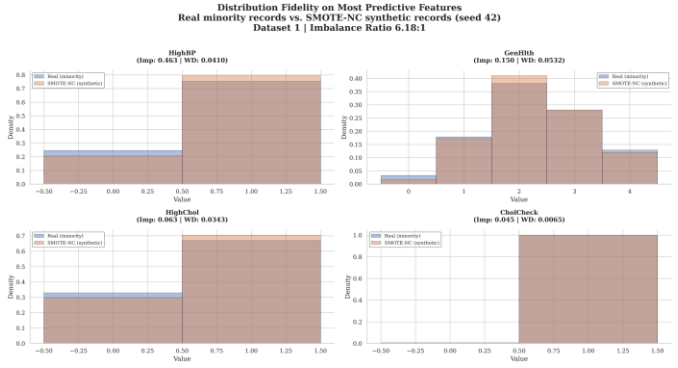

Fig. 4. Distribution fidelity of SMOTE-NC in the most predictive features of Dataset 1 (real minority vs. synthetic records).

Finally, Fig. 4 compares the real minority records of DS1 with the SMOTE-NC synthetic records (seed 42) in the four most important features (XGBoost importance on the internal training subset).

Fig. 4 shows real minority records in blue and synthetic records in orange. All distances are low (WD between 0.0065 and 0.0532), consistent with Table II, and three patterns are identified:

1) Almost perfect mimicry: In CholCheck (WD = 0.0065), 99.34% of the real and 99.99% of the synthetic records take the value 1, so the distribution is practically reproduced.

2) Reinforcement of the dominant category: In HighBP (Imp: 0.463), the most relevant feature, the share of the value 1 rises from 75.3% to 79.4% (WD = 0.0410), and in HighChol from 67.1% to 70.5%. This occurs because SMOTE-NC assigns to each synthetic record the most frequent category among its neighbours, which slightly inflates the dominant categories.

3) Ordinal smoothing: GenHlth shows the largest distance (WD = 0.0532): the central category gains weight (38.1% to 41.0%) and the extreme ones lose it (e.g., 3.3% to 1.7% in category 0), so rare values are under-represented, although the ordinal structure of the variable is preserved.

B. Evaluation of Predictive Performance (Utility Analysis)

After validating the statistical fidelity, we proceed to evaluate the predictive utility of synthetic data, understood as its ability to improve the training of classifiers in scenarios with severe imbalance. This analysis seeks to determine whether the samples generated help to better identify the minority class without significantly affecting the overall performance of the system.

The consolidated results with CatBoost are presented in Table III, and those with XGBoost in Table VII (Appendix). These values were obtained over 10 runs that regenerate the synthetic data, and they include the cost-sensitive baseline REAL-CW.

1) Ranking resilience analysis (AUC-PR): The analysis of Table III allows us to identify different behaviors depending on the level of imbalance present in each dataset:

a) Behavior in moderate ratios (DS1 to DS4): In scenarios with ratios between 2.55:1 and 6.18:1, no synthesis method improves the AUC-PR of the model trained with real data. In DS2 (Thyroid Cancer), all conditions are practically saturated (REAL: 0.9821; CTGAN: 0.9859), whereas in DS1 and DS4 all synthetic methods reduce AUC-PR significantly, with the largest losses for the deep models (e.g., DS1: 0.4242 with REAL versus 0.3482 with CTGAN and 0.3222 with TVAE).

b) Performance at the critical limit (DS5): In the scenario with a 29.99:1 ratio, the effect depends on the classifier. With XGBoost, HYBRID (0.5252 ± 0.0222) and CTGAN (0.5137) significantly exceed the baseline (0.4872; p=0.017 and p=0.021 after Holm correction); with CatBoost, no method exceeds the baseline (0.5131), and HYBRID obtains 0.4902. Moreover, the best XGBoost result remains at the level of the CatBoost baseline, so the improvement is relative to a weaker classifier and should not be interpreted as a global superiority of the hybrid method (Section IV-D).

TABLE III. PREDICTIVE PERFORMANCE ON THE TEST PARTITION WITH CATBOOST (MEAN ± SD OVER 10 RUNS)

Dataset	Ratio	Method	AUC-PR	Recall	Precision	F1-Score	Specificity	G-mean	Bal. Acc.

REAL: real data without treatment; REAL-CW: real data with class weights (cost-sensitive baseline). The results with XGBoost are reported in Table VII (Appendix)

To complement this analysis, Fig. 5 shows the evolution of the performance of the different methods as the level of imbalance increases.

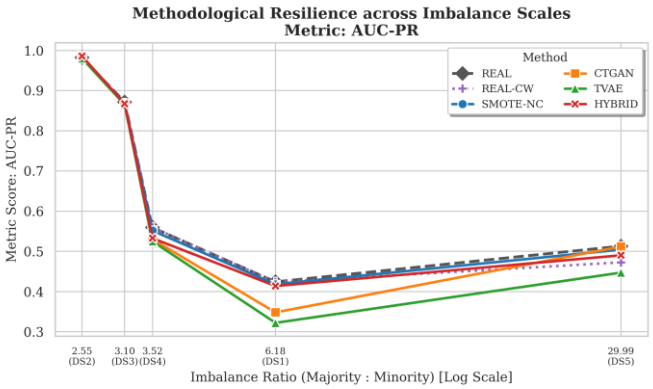

Fig. 5. Methodological resilience through imbalance scales (Metric: AUC-PR).

Fig. 5 (CatBoost) shows that the AUC-PR varies more with the dataset than with the generation method; the only significant improvements appear with XGBoost in DS5 (Table V). Fig. 6 details the differences in DS5 for both classifiers; given the small number of positive records in the test partition of this dataset (44), these differences are sensitive to a few cases.

2) Stability and fair evaluation (balanced accuracy): Because traditional Accuracy can be misleading in imbalanced scenarios, Balanced Accuracy was used to evaluate performance by considering both classes in a more balanced way.

a) Impact of balancing: Balanced Accuracy increases significantly in 21 of the 40 comparisons. In DS1, for example, CTGAN increases it from 0.5705 to 0.6937, and the cost-sensitive baseline REAL-CW reaches 0.7525. This shows that the classifier stops mainly favoring the majority class.

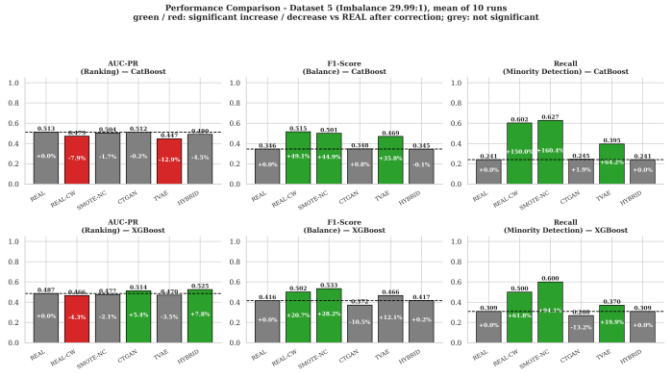

Fig. 6. Relative performance improvements among generative methods for dataset 5.

b) Behavior in the extreme scenario: In DS5, SMOTE-NC (0.7990) and REAL-CW (0.7889) obtain the highest Balanced Accuracy, followed by TVAE (0.6930), while CTGAN (0.6201) and HYBRID (0.6179) remain at the level of the baseline (0.6180).

3) Operational sensitivity and stability (recall and F1-score): The most important impact of data synthesis is observed in the model's ability to detect rare events, evaluated by Recall and F1-Score. According to the results of Table III, the use of synthetic data considerably modifies the behavior of the classifier.

a) Displacement of the decision boundary: In DS1 (Diabetes), the model trained with real data obtains a Recall of only 0.1617 ± 0.0016. By incorporating CTGAN, this value

increases to 0.5835 ± 0.0249, and REAL-CW reaches 0.7938 without any synthetic records. The hybrid approach is the most conservative (0.1781), since its final set contains only CTGAN records generated from a densified minority.

Gain in extreme scenarios (DS5): In the scenario of financial bankruptcy, SMOTE-NC obtains the largest increase in Recall, from 0.2409 to 0.6273 (CatBoost), similar to REAL-CW (0.6023), and both obtain the highest F1-Score (0.5007 and 0.5152 versus 0.3456). This improvement is accompanied by a reduction in precision. CTGAN and HYBRID do not change Recall significantly in this dataset.

As seen in Fig. 7, the F1-Score improves mainly in the scenarios where the baseline detects few positive cases (DS1, DS4 and DS5), and the largest values are obtained by REAL-CW and SMOTE-NC. In DS5, the F1-Score of the CTGAN-based methods also shows the largest variability between runs.

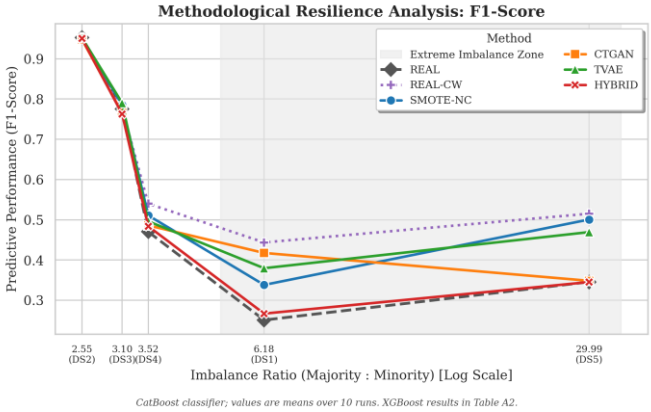

Fig. 7. F1 score across imbalance scales and methodological resilience.

4) Diagnostic quality and trade-off (precision): To complement the analysis, precision was also evaluated, a metric that allows us to measure how reliable the positive predictions made by the model are. In imbalanced scenarios, this metric is important because it helps to observe the cost of increasing sensitivity through synthetic data.

a) Relationship between precision and recall: In DS1 (Diabetes), CTGAN raises Recall to 58.3%, but reduces Precision from 0.5581 (REAL) to 0.3256; that is, about two out of every three positive predictions are false alarms. Across the 40 comparisons, Precision decreases significantly in 25 and Specificity in 27, while the G-mean, which balances Recall and Specificity, increases in 23.

b) Behavior in extreme imbalance (DS5): While SMOTE-NC reduces Precision to 0.4168 to reach a Recall of 0.6273, TVAE (0.5790) and HYBRID (0.6160) maintain a precision close to that of the baseline (0.6157), but with a smaller gain in Recall. The methods therefore move along the precision-recall trade-off rather than improving both metrics at once.

To complement this analysis, Fig. 8 shows the operating point (Recall, Precision) of each condition at the default threshold, together with iso-F1 curves. In all datasets except DS2, the synthetic methods and REAL-CW move the operating point towards higher Recall and lower Precision, and the points remain close to the same iso-F1 curves, which confirms that the main effect is a displacement of the decision threshold rather than a better separation of the classes.

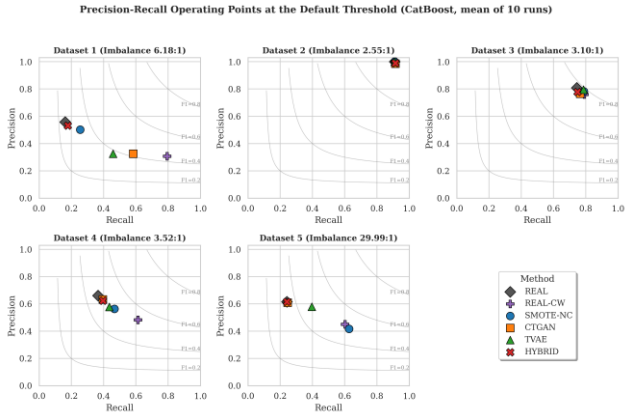

Fig. 8. Precision-Recall operating points at the default threshold (CatBoost).

5) Operational breakdown of positive detections: Fig. 9 to 13 show the mean confusion matrices over the 10 runs (CatBoost) of the baseline and of one representative method per dataset.

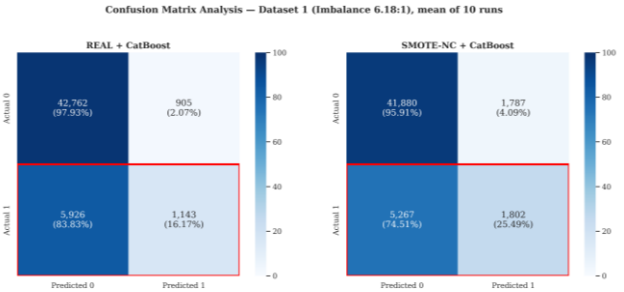

Fig. 9. Confusion matrix analysis: Dataset 1

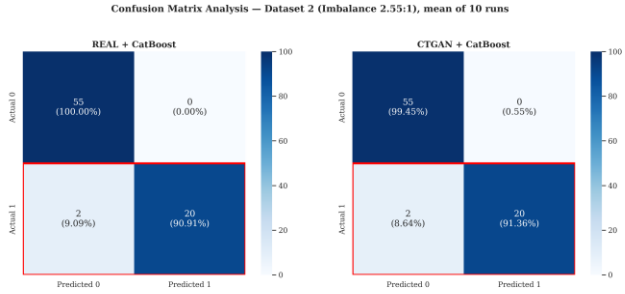

Fig. 10. Confusion matrix analysis: Dataset 2.

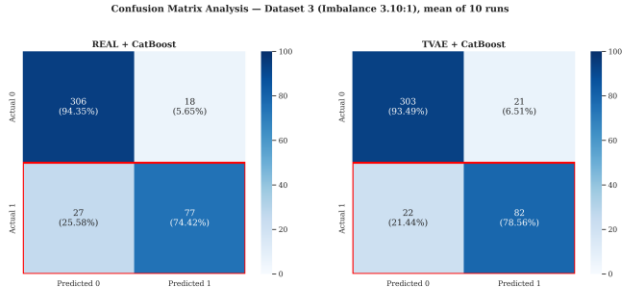

Fig. 11. Confusion matrix analysis: Dataset 3.

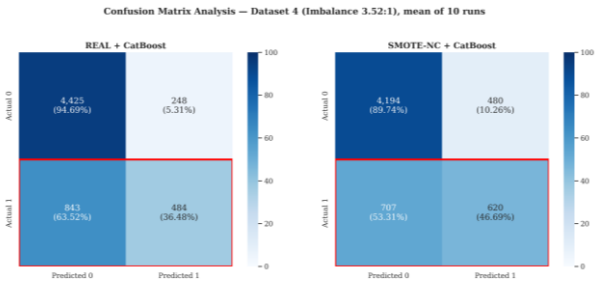

Fig. 12. Confusion matrix analysis: Dataset 4.

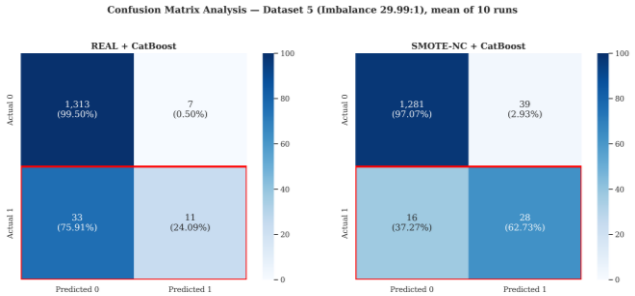

Fig. 13. Confusion matrix analysis: Dataset 5.

Scenario 1: Large-Scale Health Indicators (DS1). With an imbalance ratio of 6.18:1, the base classifier detects, on average, 1,143 of the 7,069 positive cases (16.2%). SMOTE-NC raises this number to 1,802, CTGAN to 4,125, and REAL-CW to 5,611; however, false positives grow from 905 to 8,559 with CTGAN and 12,612 with REAL-CW.

Scenario 2: Moderate Imbalance (DS2, DS3 and DS4). In DS2 (Thyroid Cancer), all conditions detect about 20 of the 22 positive cases, so synthesis does not disturb an already saturated learning. In DS3 (AIDS), SMOTE-NC and TVAE raise the detections from 77.4 to 82.0 and 81.7 of 104 cases. The largest impact of this group occurs in DS4 (Credit Default), where SMOTE-NC increases the detections from 484 to 620 of 1,327 cases, and REAL-CW to 813.

Scenario 3: Behavior at the Operational Limit (DS5). With a ratio of 29.99:1, the base model detects, on average, 10.6 of the 44 companies in bankruptcy. SMOTE-NC (27.6) and REAL-CW (26.5) more than double this number, whereas CTGAN (10.8) and HYBRID (10.6) remain at the level of the baseline. Given the small number of positive cases, each detected company represents 2.3 points of Recall.

C. Trade-Off Analysis: Statistical Fidelity Vs. Predictive Utility

Fig. 14 relates the fidelity error (Wasserstein distance) of each method to its AUC-PR (CatBoost); the dotted lines mark the medians of both axes. SMOTE-NC occupies the low-error side in all datasets, while the CTGAN-based methods move to the right, especially in DS2, DS3, and DS5.

The vertical position depends mainly on the dataset rather than on the method, and the largest fidelity errors (CTGAN and HYBRID in DS5) do not correspond to the largest losses of AUC-PR, which occur in DS1 and DS4 with moderate errors. Therefore, fidelity alone is not a sufficient predictor of utility, which reinforces the need for the dual evaluation.

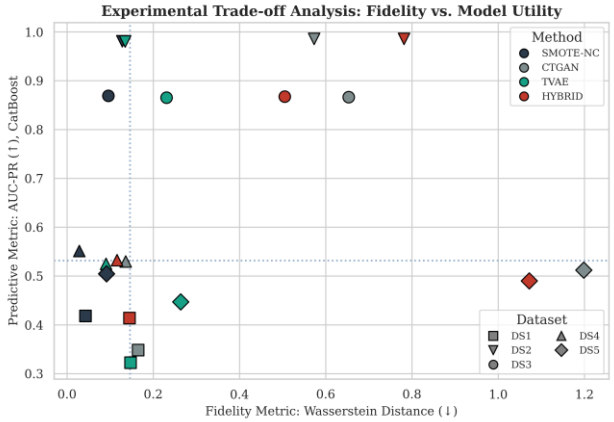

Fig. 14. Trade-off: fidelity vs. model utility.

D. Statistical Validation of Results

Tables II and III present averages and standard deviations over 10 runs, which describe the stability of each method but do not allow establishing whether the differences observed are attributable to the synthesis procedure or to random variability. To resolve this issue, the hypothesis testing protocol described in Section III-F is used. The results are summarized in Table IV.

The analysis of Table IV reveals an asymmetric pattern that substantively qualifies the interpretation of the results:

Few Improvements in AUC-PR. of the 40 Comparisons (five Datasets × Two Classifiers × Four Methods): AUC-PR Decreases Significantly in 19, Does Not Change Significantly in 19, and Increases in Only 2: CTGAN and HYBRID in DS5 with XGBoost. The decreases are concentrated in DS1 and DS4, where the four methods reduce AUC-PR with both classifiers.

Robust and Consistent Improvements in Recall. The picture is reversed when evaluating the Detection of the Minority Class. Of the 40 Comparisons, 27 Show Significant Increases in Recall, none show a Significant Decrease, 8 Are Inconclusive, and 5 Correspond to DS2, where the Metric Is Saturated. The counterpart is precision, Which Decreases in 25 Comparisons. The G-mean Increases in 23, and the F1-Score in 18, with No Significant Decrease in Either Metric.

Dependence on the Classifier in the Extreme Scenario. As shown in Table V, the Sign of the Effect in DS5 depends on the Classifier: under XGBoost, HYBRID exceeds the baseline by +0.0380 (p=0.017 after Holm correction), while under CatBoost it is below by -0.0229 (p=0.640). In addition, the XGBoost baseline (0.4872) is lower than the CatBoost baseline (0.5131), so the improvement obtained with XGBoost brings this classifier to the level of CatBoost rather than above it. A possible explanation of this reversal is discussed in Section V.

On the whole, statistical validation leads to a more accurate reading of the results: data synthesis does not improve the overall ordering of predictions measured by AUC-PR and, in several scenarios, degrades it significantly. Its contribution is concentrated in a reproducible displacement of the decision boundary towards the minority class, which translates into increases in Recall and G-mean of large magnitude, at the cost of Precision and Specificity.

TABLE IV. STATISTICAL VALIDATION: MEAN DIFFERENCE WITH RESPECT TO REAL (Δ), SIGNIFICANCE AND EFFECT SIZE D_Z (N = 10 PAIRED RUNS, SAME CLASSIFIER)

Cell format: Δ with significance (effect size d_z). *** p<0.001; ** p<0.01; * p<0.05; no mark: not significant. p-values from the paired t-test, or from the Wilcoxon signed-rank test when Shapiro-Wilk rejects the normality of the differences, with Holm correction within each family of four synthetic methods (same dataset, classifier and metric). REAL-CW is tested separately without correction. 0 (—): identical results in all runs (metric saturated). Complete results for all metrics, confidence intervals and uncorrected p-values are available from the corresponding author upon request.

TABLE V. DECOMPOSITION OF THE DS5 SCENARIO (AUC-PR) BY CLASSIFIER (MEAN ± SD OVER 10 RUNS)

Method	CatBoost	Δ vs REAL	p (Holm)	XGBoost	Δ vs REAL	p (Holm)
REAL	0.5131 ± 0.0245	—	—	0.4872 ± 0.0173	—	—
REAL-CW	0.4727 ± 0.0286	-0.0404	0.017†	0.4662 ± 0.0176	-0.0210	0.043†
SMOTE-NC	0.5045 ± 0.0264	-0.0086	0.822	0.4768 ± 0.0101	-0.0104	0.246
CTGAN	0.5119 ± 0.0268	-0.0012	0.922	0.5137 ± 0.0162	+0.0265	0.021
TVAE	0.4472 ± 0.0220	-0.0659	<0.001	0.4704 ± 0.0300	-0.0168	0.246
HYBRID	0.4902 ± 0.0514	-0.0229	0.640	0.5252 ± 0.0222	+0.0380	0.017

Δ vs REAL: mean difference compared to the baseline trained with the same classifier. The p-values are corrected with Holm within each classifier; † REAL-CW: uncorrected p-value.

Comparison with the Cost-sensitive Baseline. REAL-CW Significantly Increases Recall in All Non-saturated Comparisons (e.g., DS1: from 0.1617 to 0.7938) without the substantial loss of AUC-PR observed with the synthetic methods in DS1 and DS4, and it obtains the highest F1-Score and G-mean in DS1 and DS4; in DS5 it is comparable to SMOTE-NC.

V. Discussion

Together, the results show that data synthesis does not work the same in all cases, but rather depends on the type of dataset, the level of imbalance, and how much information is actually available. In terms of fidelity, SMOTE-NC performs better when the data has a well-defined numerical part, and the imbalance is not as extreme as in DS1. There, it manages to maintain the structure of the data well with a low Wasserstein Distance, which basically shows that interpolation works well when the database is "stable". On the other hand, when the scenario becomes more complicated and there are many categorical variables, as in DS2, the CTGAN-based methods (HYBRID and CTGAN) reproduce the categorical proportions better, which is consistent with the conditional generator of CTGAN, designed to sample the categories of discrete columns in a balanced way [37].

When moving to predictive utility, the statistical validation of Section IV-D forces us to distinguish two planes that initially seemed to be one. In DS5, HYBRID and CTGAN improve the AUC-PR of XGBoost significantly (HYBRID: 0.5252 versus 0.4872) but not that of CatBoost, and they do not exceed the best baseline; the hypothesis that synthesis improves the global ordering under extreme scarcity is therefore only partially supported. The consistent effect is on sensitivity: CTGAN raises Recall in DS1 from 0.1617 to 0.5835, and SMOTE-NC in DS5 from 0.2409 to 0.6273. This suggests that the real contribution of the synthesis is to relocate the decision boundary to regions where the base model lacked information to risk a positive prediction.

This interpretation is reinforced by REAL-CW, which produces a similar or larger displacement without generating records, since oversampling and class reweighting act on the same mechanism: the relative weight of the minority class in the loss.

The dependence on the classifier in DS5 admits two explanations. First, the differences (0.023 to 0.038 in AUC-PR) are of the same order as the variability between runs, and the test partition contains only 44 positive records. Second, CatBoost builds symmetric trees, which limit the isolation of small regions, whereas XGBoost grows asymmetric trees that can exploit the dispersed CTGAN records in 95 dimensions; moreover, the XGBoost baseline is weaker in this dataset. This second explanation is a hypothesis, not a verified mechanism.

Regarding extreme imbalance, the generators learn from 22,622 minority records in DS1 but only 141 in DS5 (about 1.5 per feature) and 69 in DS2. This explains the large fidelity errors of the deep models in DS5 and DS2, and why SMOTE-NC, which only interpolates between existing neighbours, obtains the largest gain in Recall in DS5. The behavior in DS5 therefore reflects extreme imbalance, a very small minority class, and high dimensionality together, and, being the only dataset above 20:1, it should be confirmed in additional datasets.

In this sense, the hybrid SMOTE-NC-CTGAN approach is the most conservative synthetic method: it keeps precision close to the baseline and loses less AUC-PR than CTGAN and TVAE in DS1, but its gain in Recall is small, and its only significant improvement in AUC-PR appears in DS5 with XGBoost. SMOTE-NC is the most reliable option when the minority class is reasonably represented.

From a practical point of view, this displacement has a cost: in DS1, CTGAN lowers Precision from 0.56 to 0.33, so about two out of three positive predictions are false alarms, which may mean unnecessary clinical tests or the rejection of solvent clients. The choice of method should therefore consider the relative cost of both errors, and reweighting the classes should be considered first, since it obtains a similar displacement at a lower cost.

Of course, the study was not free of limitations. The datasets come from a curated repository (UCI) with few missing values and little noise, so the patterns may differ in messier real-world health and finance data [11]; only one dataset exceeds 20:1; the hyperparameter grid of the generators was small [9], [20]; and a single train/test partition and the default threshold were used. Finally, privacy was not addressed; future work should include multi-class problems and differential privacy.

VI. Conclusion

From the results obtained, several conclusions can be drawn about the impact of data synthesis on imbalanced classification problems: Dependence on the Ratio and Behavior under Extreme Imbalance: the Performance of Synthesis Techniques Depends Directly on the Level of Imbalance. SMOTE-NC Preserves the Structure of the Data Best in All Scenarios and Is the Most Reliable Option in Moderate Imbalance. When the Imbalance Is Extreme (29.99:1), CTGAN and the Hybrid Approach Significantly Improve the AUC-PR of XGBoost but Not that of CatBoost, and They Do Not Exceed the Best Baseline; This Behavior Is Therefore Classifier-dependent. This Scenario Is Represented by a Single Dataset with a Very Small Minority Class, Which Limits the Generality of This Conclusion.

Diversity Must Be Interpreted Together with Fidelity: in High-scarcity Scenarios, the GAN-based and Hybrid Models Generate the Most Diverse Records, but This Diversity Coincides with the Largest Fidelity Errors and Translates into a Significant Gain in AUC-PR Only in One Scenario (DS5 with XGBoost). Therefore, Diversity Alone Is Not an Indicator of the Usefulness of Synthetic Data.

Hybrid Approach Balance: the SMOTE-NC-CTGAN Model Is the Most Conservative of the Synthetic Methods: it Keeps Precision Close to that of the Baseline and achieves the Only Significant Improvements in AUC-PR, together with CTGAN, in the Most Critical Scenario with XGBoost (DS5: 0.5252 Versus 0.4872). However, Its Gain in Recall Is Small, and Its Advantage Depends on the Classifier, so Its Merit Lies in This Specific Scenario and Not in a General Superiority over the Baseline.

Improvement in the Detection of the Minority Class: Finally, and as a Main Result of This Research, it Is Concluded that Data Synthesis Improves the Model's Ability to identify the Minority Class in a Statistically Robust Way. Recall Increases Significantly in 27 of 40 Comparisons and Never Decreases, at the Cost of AUC-PR and of Precision (lower in 25); Reweighting the Classes Achieves a Comparable Displacement. This Trade-off Is Favorable Where the Cost of a False Negative Dominates, Such as in clinical diagnosis and Credit Risk, and must be weighed against the Cost of False Alarms.

A Deep Learning-Based Real-Time Surveillance Framework for Mitigating Herbivorous Animal Intrusions in Rice Nursery Fields

Muhammad Juman Jhatial, Riaz Ahmed Shaikh, Rafaqat Hussain Arain
Institute of Computer Science, Shah Abdul Latif University, Khairpur Mirs, Sindh, Pakistan

***Abstract*—The rice nursery stage is a very critical stage of the rice growing cycle, as intrusion of herbivorous animals can lead to substantial economic losses and yield losses. Manual guarding and physical fencing are inefficient and ineffective. Real-Time Animal Intrusion Detection Network (RAID-Net) is an end-to-end intelligent agricultural surveillance system that consists of an integration of YOLO and a multi-task CNN to detect and recognize herbivorous animal intrusion in open-field rice nursery fields in real time. To this end, a novel and perfectly balanced dataset of 14,000 images with five different herbivore species (Buffalo, Camel, Cow, Goat, and Sheep) was curated, and a variety of seven YOLO models and five CNN architectures were benchmarked to identify the optimal detection and classification backbones. The model design includes a lightweight YOLOv8 Nano object detector and a custom-designed Multi-task Convolutional Neural Network (CNN) for species classification and behavior detection grazing and moving. The results of the Customized Multi-task CNN on cropped animal regions showed 97.72% species classification accuracy and 98.14% behaviour recognition accuracy. The RAID-Net with YOLO detection-aware alert pipeline yielded 90.05% species accuracy, 94.31% behaviour accuracy, and 82.73% hybrid accuracy, with an end-to-end latency of 17.61 ms and an inference rate of 56.79 FPS on edge-compatible hardware with an alert precision of 98% and recall of 89%. The system differentiates between high-threat grazing and low-threat moving behaviors, automatically activating a siren deterrent and sending instant WhatsApp/SMS alerts to farmers, providing an automated, scalable, and very accurate solution for precision agriculture and crop protection.**

Keywords*—Precision agriculture; deep learning; Yolo model; convolutional neural networks

I. Introduction

Rice farming is the basic livelihood activity for food security in Pakistan and plays a significant role in rural economies. The nursery stage is crucial for the establishment of seedlings, with a duration of 20-30 days.

At this time, rice plants are delicate and prone to grazing and trampling by domestic herbivorous animals [1]. Out of many herbivorous animals, five such animals were chosen for this study as they are seen with regularity in rice nursery fields and have a marked effect on the damage to the crop (Buffalo, Camel, Cow, goat, and Sheep). Illustrated in Fig. 1.

Fig. 1. Dataset images.

The rice nursery stage is one of the most critical periods of the rice production cycle, especially in open field conditions where the intrusions of herbivorous animals may lead to damage to young seedlings, which may be irreversible and fast. Domestic animals like buffalo, camel, cow, goat, and sheep often intrude into the nursery fields for food and have strong grazing ability, which easily strips newly planted rice plants, resulting in huge economic losses for farmers in many rural agricultural areas. Current protection measures are often traditional, reactive, and labour-intensive, such as manual guarding, fencing, and scare devices [2]. They are labour-intensive, time-consuming, and difficult to scale up to large areas of agriculture, particularly when animals can be in fields without being monitored and cannot be seen at night or in unsuitable weather. Recently, computer vision and smart agriculture technologies have emerged with potential, but most of the proposed methods are either object detection or species classification and fail to consider behavior analysis, severity assessment of intrusions, and automatic alert generation. Hence, there is a critical need for a specialized end-to-end intelligent surveillance framework that can detect, identify, and assess threats based on species behavior for proactively protecting the rice nursery field in real-time and enhancing agricultural resilience.

A. Computer Vision and Deep Learning

The past few years have seen tremendous progress in computer vision and deep learning, which has led to the development of robust object detection and image classification algorithms that can perform these tasks in real time with high accuracy in challenging scenarios. In agriculture, intelligent systems can also be used to replace manual field supervision using the detection and tracking of animals like cows, goats, and buffalo in rice paddy fields, as shown in Fig. 2, which is a promising solution for agricultural monitoring.

Fig. 2. Computer vision system monitoring a rice paddy field.

However, the existing agricultural monitoring frameworks are still limited in their functions. Many systems are limited to the mere detection of animal movement, and not necessarily on the basis of what it means in terms of animal behavior, which makes it challenging to distinguish harmless animal movement from destructive grazing behavior. On the other hand, there are also studies that focus on species classification but do not have the capability of spatial localization because they work on images that have been pre-segmented or cropped instead of identifying the animals in large-scale real scenes in the agricultural field. Consequently, existing methods focus on detection or classification only, and there is a significant research gap in how to combine spatial localization with species identification and behaviour understanding into a single entity. Considering this shortcoming, this study presents a comprehensive deep learning-based surveillance system, especially for protecting the rice nursery field. An annotated herbivore intrusion dataset of five domestic animals was built to facilitate training and evaluation of the model. Various detection models and CNN architectures based on YOLO were extensively benchmarked to choose the best configurations considering the accuracy, inference speed, and computational efficiency. Based on the above results, a new hybrid model fused YOLO for detection and a multi-task CNN for classification, which can simultaneously localize, identify the species, and recognize the behaviors of the animals, was constructed. Moreover, a behavior-aware threat assessment mechanism was added to distinguish the difference in movement between the animal moving and the destructive use of the animal to graze, enabling context-aware decision-making. Last but not least, a real-time alert and deterrence pipeline was put in place, comprising automated siren activation and mobile notifications to enable farmers to respond immediately, rather than relying on passive observation, leading to a shift from passive monitoring to proactive crop protection.

II. Related Work

The integration of artificial intelligence (AI), machine learning (ML), and deep learning (DL) in agriculture has emerged as an effective solution to challenges related to population growth, climate change, and resource scarcity, improving crop management, resource optimization, and pest control. In this comprehensive review, the authors investigate the potential of machine learning and deep learning applications for agricultural use. Food security is still defined largely by crops, livestock, and fisheries, but these are subjected to serious challenges including climate variability, scarcity of resources, and sustainability issues. Recent research has shown that AI can be used to solve problems, from simple machine learning to more complex deep learning and vision-language models, in various fields like crop disease detection, livestock health monitoring, and aquatic species management. Yet, challenges such as data variability, scalability constraints, and deployment constraints underscore the importance of multimodal data integration and flexible AI solutions for a variety of farming contexts.

A. AI in Agriculture: A Survey of Deep Learning Techniques for Crops, Fisheries and Livestock.

Consequently, deep learning has emerged as a significant technology in precision agriculture, especially when it comes to the early detection of crop diseases that pose threats to yield and quality. This study used multi-modal approaches on potato, tomato, grape, apple, and peach leaves and found that VGG16, MobileNetV2, Xception, and ResNet all performed quite well, with the metrics of Accuracy, Precision, Recall, and F1-Score. The findings indicate that VGG16 achieved 99% efficiency, suggesting that scalable, non-invasive AI systems could provide valuable plant disease management tools, all supported by farmer trust in AI systems.

Judging from the title, the authors have a very creative methodology for enhancing agricultural disease detection. Judging from the title, the authors have a very creative methodology for enhancing agricultural disease detection.

Food sustainability is a growing global challenge due to rapid urbanization and globalization, and AI systems can provide new solutions to improve productivity and food security. Crop Diseases like chlorosis continue to pose a significant threat in India, where more than half of the population relies on agriculture for their livelihood, despite significant strides in the past, including the Green Revolution. The existing detection method has shortcomings in accuracy, and deep learning technology is a more reliable and scalable solution for disease detection in the context of variable environments and climates.

B. Leveraging Deep Learning and Neural Networks for Real-Time Crop Monitoring in Smart Agricultural Systems Srinivas Kalyan Yellanki

Precision agriculture and plant disease diagnosis rely heavily on early detection and accurate diagnosis, especially when plant diseases are a significant threat to food security worldwide. In recent years, studies have emerged that show the ability of computer vision and deep learning methods such as CNNs, transformer vision, and GANs combined with imaging technologies like RGB, multispectral, and hyperspectral sensors. A great deal of research reviews have documented progress and identified challenges associated with the use of these models and have offered useful insights on how these models are applicable for sustainable agricultural production. The use of deep learning and computer vision has been proposed as a comprehensive review of the techniques, models, and trends in precision agriculture for the purposes of plant disease detection. Deep learning and computer vision in plant disease detection: a comprehensive review of techniques, models and trends in precision agriculture. Artificial Intelligence (AI) and Deep Learning (DL) are two technologies that have the promise of revolutionizing agriculture and offering new solutions to some of its biggest problems, including productivity, sustainability, labour shortages, and environmental monitoring. Intelligent systems, such as computer vision, machine learning, and edge computing, have been developed to perform various tasks like crop classification, weed and pest detection, yield estimation, soil health analysis, and automatic irrigation control, etc., in recent years [1, 2]. Although these all yield different results, deep learning, particularly using Convolutional Neural Networks (CNNs), has been very effective for image processing applications such as plant disease recognition, fruit grading, phenol typing, livestock monitoring, and more [3] [4]. For object detection in real time, there are some popular frameworks like YOLO (You Only Look Once), Faster R-CNN, and SSD (Single Shot Multi-Box Detector) which are used for agriculture-related objects like plant, pest, fruit, and animal object detection [5]. The models can be used in precision agriculture: automatic identification and localization of certain entities in images or real video. Furthermore, AI-driven Unmanned Aerial Vehicles (UAVs), autonomous tractors, and robotic harvesters have started to change the dynamics of field operations, making them more data-informed and independent in how they are conducted. Moreover, Recurrent Neural Networks (RNNs) and LSTM models are applied to time series prediction tasks such as prediction of the weather, crop yield, irrigation scheduling, etc. [6]. But there remains a whole host of issues to be resolved, including: availability of large annotated data sets; regional and seasonal generalizability of models; ability to deploy models on low-cost edge devices suitable to rural environments. While there have been significant advances in crop and disease detection, the ability to detect livestock and/or animal incursions in some high-risk sites, e.g., rice nurseries, has not been well explored. This points to the need to develop more specialized and domain-specific deep learning systems to address the technical and practical issues in the agri-environment. 2.2 Animal detection or monitoring systems in place. The traditional methods of animal counting are still challenging in livestock management, and drone-based methods are also not easy. This study presents the Mask YOLOv7, an advanced object detection and instance segmentation model, for detecting and counting cattle in both controlled and uncontrolled settings, such as feedlots and open ranges. The experiment results reveal that the model has high accuracy of 93% and 95%, respectively, which makes it possible to apply it in livestock inventories and monitoring and also in intelligent farm management applications. Drone Vision System for Automated Cattle Detection and Counting using Mask YOLOv7 is an innovative technology that aims to monitor cattle from a distance using an unmanned aerial vehicle (UAV). Despite the importance of cows in daily life and nutrition, especially in India, maintaining healthy cows can be a big problem, and lameness is one of the most costly problems in dairy herds. This study introduces a Smart Cow Health Monitoring System (ScHeMoS) that uses an IoT sensor system and, in particular, the LSTM deep learning model to analyze the behavior and physiological parameters of the cow for the early detection of lameness. The model showed good accuracy of 92.45% and an F1 score of 0.92 on the self-collected set, suggesting its potential feasibility for practical farm management and animal welfare practices.

C. Schemos Smart Cow Health Monitoring System: An IoT-Based Cow Hoof Detection And Healthcare Alert System Using LSTM Network

Regularly checking on a pet is very important to lower health risks, but checking on external behavior can be misleading. In this study, a video-based monitoring system that extracts behavioral features from the image, detects anomalies, and alerts to deviations from common behavior is proposed using Mask R-CNN. Hamster experiments showed the effectiveness of the system in recognizing abnormal and normal movements, and future work plans involve increasing the sensitivity of the system to move towards recognizing more subtle movements. Monitoring systems for animals based on behavioral information and internal state information. Regularly checking on pets is important to minimize health risks, but often external behavior is a poor indicator of internal condition. In this study, a video-based monitoring system with Mask R-CNN was proposed to obtain behavioral features and detect anomalies, making alerts whenever there are anomalies in the behaviors. Experimental tests with hamsters showed the efficacy of the system to discriminate between "normal" and "abnormal" behaviors, and further developments would involve increasing the sensitivity of the system to subtle movements.

D. Research on Behavior Recognition and Online Monitoring System for Liaoning Cashmere Goats Based on Deep Learning

Automated cameras (e.g., camera traps) are also deployed for wildlife monitoring, but there are some limitations in their effectiveness, including imperfect detection, limited storage, and power supply. This work introduces a customizable camera system with YOLOv5 integrated into a Raspberry Pi, which is used for continuous monitoring of fast-moving organisms in field conditions and is demonstrated in mason bees. The system was proven to be reliable, with an average detection precision of 78%, and it was found to be a low-cost, modular, and researcher-friendly solution to commercial camera traps. Monitoring high-speed animals, creating a specific camera system, and developing an evaluation toolset.

In the past few years, the detection and monitoring of animals has become a rising concern, especially in the fields of livestock management, wildlife conservation, and agricultural protection. There are a large number of works that used deep learning methods, including convolutional neural networks (CNNs) and object detection methods like YOLO (You Only Look Once), SSD (Single Shot Detector), and Faster R-CNN to detect animals in images or video streams [1],[2]. These are usually used to monitor open pasture areas [3], forest areas [4], or urban wildlife zones [5]. Although they have shown promising results in detecting animals like cattle, deer, or wild boars, most of the existing models are developed for generalized detection tasks, e.g., animal/non-animal or livestock/wildlife.

Moreover, the current animal monitoring systems are typically designed for controlled conditions, high-quality video resolution, and background stability, which are seldom observed in the real agricultural environment [6]. Many models are unable to be optimized for inference speed on edge devices, making it difficult to obtain a good accuracy rate. There is a lack of lightweight architectures and applications that are mobile-friendly and suitable for real-time application, especially in rural rice fields [7].

Furthermore, the problem of species-level identification of herbivorous animals (buffalo, cow, goat, sheep, and camel), which are visually similar in some aspects, is significant for prioritizing alerts based on the severity of crop damage, and few studies address this issue. In the same way, in the majority of works, behavioral analysis, including animal movement tracking or prediction of grazing, is still not well studied. Some work has used GPS collars or radio frequency identification (RFID) to track livestock [8], but such methods are not scalable and not suitable for free-roaming livestock entering rice fields. There is also a lack of real-time farm monitoring solutions, including the use of early warnings via SMS or mobile app, which further diminishes the usefulness of these solutions in practice [9].

III. Materials and Methods

A real-time deep learning-based surveillance framework, RAID-Net, is proposed to protect rice nursery fields from domestic herbivorous animal intrusions like buffalo, camels, cows, goats, and sheep. The architecture is built on a multi-stage pipeline architecture with integration of object detection, behavioral analysis, and automated response mechanisms, as shown in Fig. 3.

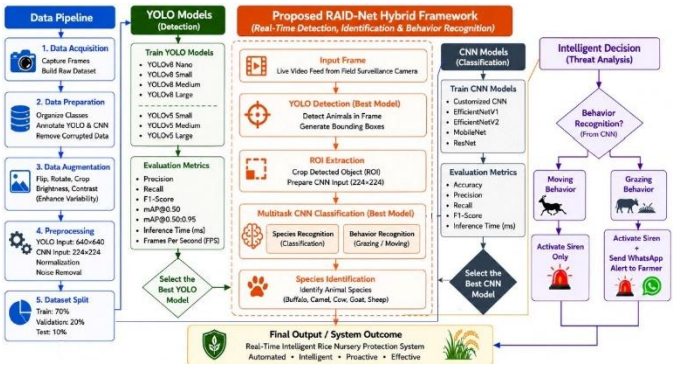

Fig. 3. Flowchart of research methodology and development pipeline.

This figure shows the five major steps in the research lifecycle: (Phase 1), Data Pipeline (acquisition and augmentation), YOLO testing and benchmarking (Phase 2), and CNN testing and benchmarking (Phase 3). It also explains the incorporation of these models in the RAID-Net (Phase 4). The final logic-based alert generation system (Phase 5) for protection of rice nursery fields.

A. Phase 1: Data Pipeline

The data pipeline can be used to systematically move images from acquisition to preprocessing to model inference, which makes it easy to detect and identify herbivorous animals (Fig. 4).

B. Data Collection

The data set contains a total of 14000 RGB images from various sources, such as rural field areas, open grazing areas, and publicly available data sets [14, 15, 16, 17]. The images are classified into 5 classes: Buffalo, Camel, Cow, Goat, and Sheep, and each class contains approximately 2800 images, which is a nice balance for training and testing of the model. Shown in Tables I and II.

TABLE I. Dataset Acquisition Characteristics

Source	Geographic location	Acquisition	Device source	Day/Night	Images
Rural field dataset	Larkana, Sindh, Pakistan	Field	Digital camera	Day	3,420
Open grazing dataset	Dadu, Sindh, Pakistan	Field	Smartphone	Day	3,680
Public Dataset A	Kaggle.com	Public dataset	Internet	Variable	3,510
Public Dataset B	Shutterstock.com	Public dataset	Internet	Variable	3,390
Total					**14000**

Fig. 4. Raw images.

TABLE II. CLASS-WISE DISTRIBUTION OF DATASET

Animal Class	Number of Images
Buffalo	2800
Camel	2700
Cow	2900
Goat	2700
Sheep	2800
Total	14000

C. Dataset Annotation and Labelling

The full set of data is systematically annotated and labelled for object detection using YOLO as well as CNN for classification. In the case of the YOLO models, the instances of animals in the whole dataset were manually cropped, and the class labels were manually assigned to the cropped objects. By having this annotation and labelling procedure, the data preparation and class representation for both the detection and the classification phases of the proposed framework were consistent [10], [11]. The dataset labelling is illustrated in Fig. 5 for classification models.

Fig. 5. Dataset labelling.

D. Dataset Splitting for Model Development.

To support proper model development, we divided the dataset as follows: 70% for training, 20% for validation, and 10% for testing [12], [13]. This is illustrated in Fig. 6 and Table III.

Fig. 6. Dataset splitting.

TABLE III. DATASET DISTRIBUTION FOR TRAINING, VALIDATION AND TESTING

Dataset Split	Percentage	Number of Images
Training set	70%	9800
Validation set	20%	2800
Testing set	10%	1400
Total		14000

E. Images Preprocessing and Augmentation

Pre-processing of images was done to prepare them for model training. This involved resizing the images to 640X640 for the YOLO model and 240X240 for the CNN model, and then normalizing the images. To improve the model's robustness and generalization, as shown in Fig. 7, data augmentation methods like horizontal flipping, brightness variations, and random cropping techniques were employed. Horizontal flipping, 15% brightness, and resizing are preprocessing steps [18],[19],[20].

Fig. 7. Data preprocessing and data augmentation.

F. Phase 2: Detection Module (YOLO)

The Detection Module in the proposed RAID-Net framework is based on the YOLO architecture [21]; Fig. 8 shows the YOLO Architecture below.

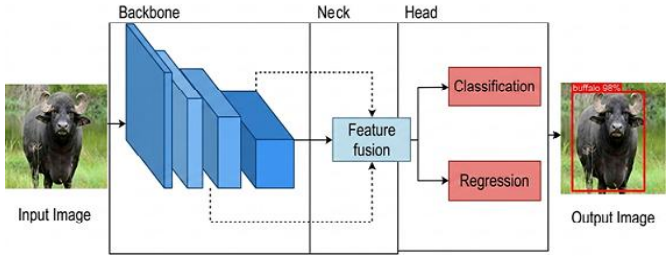

Fig. 8. YOLO architecture.

The system starts with a high-resolution camera that takes images from the field, which are then resized to 640×640 pixels and then represented as:

$$I \in R^{640\times640\times3}$$

The YOLOv8-Nano detector works on the input image and outputs a list of bounding boxes, confidences, and class probabilities:

$$f_{YOLO}(I) = \{B_i, C_i, S_i\}_{i=1}^{N}$$

where, B_i denotes the bounding box coordinates, C_i represents the confidence score, and S_i indicates the class probability for the ith detected object.

The composite loss function is used for the YOLO model:

$$L_{YOLO} = L_{BOX} + L_{OBJECT} + L_{CLS}$$

where, L_{BOX} represents bounding box regression loss, L_{OBJECT} denotes objectness loss, and L_{CLS} corresponds to classification loss. Together, they optimize the model to get accurate localization and reliable detection. Real-time agricultural surveillance of herbivorous animals that can be detected and effectively classified.

G. Phase 3: Multi-Task CNN Module (Species and Behavior Classification)

The Multi-Task CNN Classification Module is shown in Fig. 9 of the CNN model architecture [22].

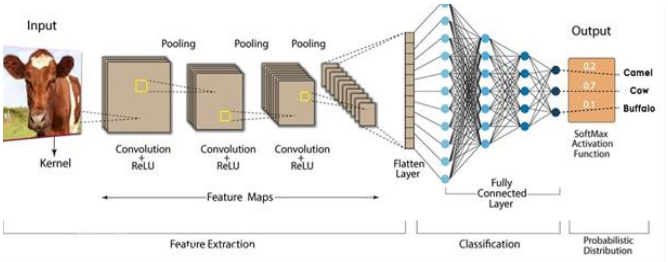

Fig. 9. CNN Architecture.

CNN-based classification stage for the RAID-Net framework:

$$F = CNN(ROI), \quad P_s = Softmax(W_s F + b_s), P_b = Softmax(W_b F + b_b)$$

$$L_{total} = \lambda 1 L_{species} + \lambda 2 L_{behavior}$$

F = feature vector from the cropped ROI (240 × 240 pixels)

P_s, P_b = predicted probabilities for species and behavior

W_s, b_s, W_b, b_b = classifier parameters

L_{total} = weighted multi − task loss balancing species and behavior learning

H. RAID-Net and Alert Phases

$$\text{Alert} = \begin{cases} Higt - Priority\ if\ S_{SPECIES} = Animal, S_{Behaviour} = Grazing, C_{Hybrid} \geq T_{Threshold} \\ Meduim - Priority\ if\ S_{SPECIES} = Animal, S_{Behaviour} = Moving, C_{Hybrid} \geq T_{Threshold} \end{cases}$$

$$\text{Response} = \begin{cases} Grazing: Acitvate\ Siren + Send\ WhatsApp\ Alert \\ Moving\ Activate\ Siren \end{cases}$$

$S_{species}$, $S_{behavior}$ = predicted species and behavior

C_{hybrid} = hybrid confidence score from fusion layer

$T_{threshold}$ = minimum confidence to trigger an alert

The outputs are connected to the real-world system, such as the siren hardware and WhatsApp API, allowing real-time deterrence and remote farmer notification. This is a combination of AI and rules, providing both reliability in operations and readability in agricultural field deployments. The RAID-Net architecture is shown in Fig. 10.

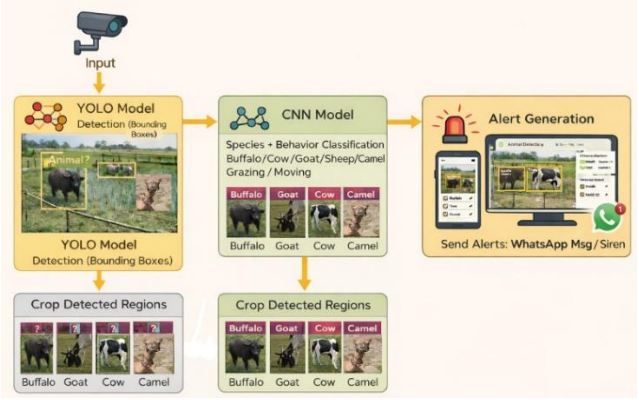

Fig. 10. Architectural framework of RAID-Net.

The diagram shows the actual operation of the surveillance system from the acquisition of the video stream from the input camera. It illustrates the multi-step process of passing the output of a YOLO model for object localization through a CNN model for fine-grained species and behavior classification, and then to either automated WhatsApp alerts or audible sirens, depending on the intrusion detected.

IV. Experimental Setup

To ensure the flexibility and scalability of the experimental setting, the proposed RAID-Net framework was implemented on cloud-based GPU platforms as well as a local computational system to facilitate reproducibility of the experiment. The implementation of YOLO based detection models and integration experiments in a hybrid setup consisted of using Google Colab with Python 3 and NVIDIA Tesla T4 GPU acceleration, which proved to be the most effective for training the YOLOv5 and YOLOv8 architectures with PyTorch and the Ultralytics framework. The multi-task CNN classification experiments were conducted on Kaggle Notebooks using GPU-enabled environments (P100/T4) that are optimized for deep learning tasks, with TensorFlow and Keras APIs for developing the models and hyperparameter tuning [23]. We also validated and tested the model on a local system with an Intel Core i5 (12th Generation) CPU, 16 GB of RAM, 250 GB SSD storage, and an NVIDIA graphics card for model inference, lightweight training, and system-level integration. It integrates computing infrastructure to ensure stability in handling the datasets, faster speed for model training, and repeatability of the performance evaluation across different hardware configurations.

TABLE IV. YOLO Training Configuration

Category	Parameters	Values
Model Settings	Base Model	YOLOv8x
	Task	Object Detection
	Image Size	640 × 640
	Epochs	100
Optimization	Optimizer	SGD
	Initial Learning Rate	0.01
	Momentum	0.937
	Weight Decay	0.0005
Hardware / Device	GPU	NVIDIA(CUDA enabled)
	CPU	Intel Core i5 12th Gen
	RAM	16 GB
	Storage	250 GB SSD
	Workers	8
Data Augmentation	HSV Hue	0.015
	HSV Saturation	0.7
	HSV Value	0.4
	Horizontal Flip	0.5
	Mosaic	1.0
Dataset	Data Configuration	data.yaml

This specific YOLOv8x model was optimized for 100 epochs with 16 images per batch and an input resolution of 640×640 pixels. The optimizer used was SGD with an initial learning rate of 0.01, a momentum of 0.937, and a weight decay of 0.0005. To enhance generalization, data augmentation methods were used, such as HSV color augmentation, horizontal flipping, and mosaic augmentation. All experiments were carried out on an Intel Core i5 (12th Generation) system with 16 GB of RAM and NVIDIA GPU acceleration, as shown in Table IV.

TABLE V. CNN MODEL CONFIGURATION AND TRAINING PARAMETERS

Category	Parameter	Value
Architecture	Backbone	Custom CNN
	Input Size	224 × 224
	Species Classes	5
	Behavior Classes	2
	Dropout	0.5
Optimization	Optimizer	Adam
	Learning Rate	0.001
	Weight Decay	0.0001
Loss	Species Loss	Cross Entropy
	Behavior Loss	Cross Entropy
	λ_1 (Species)	1.0
	λ_2 (Behavior)	1.0
Training	Epochs	100
	Batch Size	16
Hardware	GPU	NVIDIA CUDA
	RAM	16 GB

Table V illustrates that the proposed custom CNN model has an input size of 224 x 224. It has 5 classes for species and 2 classes for behavior. To avoid overfitting, a dropout layer with a rate of 0.5 is used [24,25]. The network is trained with the Adam optimizer, learning rate = 0.001 and weight decay = 0.0001. Both the loss function for the species and the loss function for the behavior classification are cross-entropy with λ_1 = 1.0 for species and λ_2 = 1.0 for behaviour classification. Training is done for 100 epochs, using a batch size of 16. All experiments are run on a system with an NVIDIA CUDA GPU and 16 GB of RAM.

Table VI shows that the CNN model has three convolutional blocks with an input size of 224×224×3. A block consists of a convolutional layer (3×3) and a ReLU activation followed by a max-pooling layer (2×2). There are 32, 64, and 128 filters in the convolutional layers, respectively. The feature maps are then flattened (86,528 units) and fed into a fully connected dense layer with 256 units, with a dropout layer with a rate of 0.5 to avoid overfitting. Finally, two parallel dense layers are used as outputs: species classification (5 classes) and behaviour classification (2 classes), both with Softmax activation. The total number of trainable parameters is 22,246,471 (~84.86 MB).

TABLE VI. PARAMETERS OF MULTI-TASK CNN MODEL

Layer (Type)	Output Shape	Parameters	Description
InputLayer	(224×224×3)	0	Input image
Conv2D (3×3, 32)	(222×222×32)	896	ReLU activation
MaxPooling2D (2×2)	(111×111×32)	0	Pooling layer
Conv2D (3×3, 64)	(109×109×64)	18,496	ReLU activation
MaxPooling2D (2×2)	(54×54×64)	0	Pooling layer
Conv2D (3×3, 128)	(52×52×128)	73,856	ReLU activation
MaxPooling2D (2×2)	(26×26×128)	0	Pooling layer
Flatten	86,528	0	Flatten feature maps
Dense (256)	256	22,151,424	Fully connected layer, ReLU
Dropout	256	0	Dropout 0.5
Dense (5)	5	1,285	Species classification (Softmax)
Dense (2)	2	514	Behavior classification (Softmax)

Total parameters: 22,246,471 (~84.86 MB)
Trainable parameters: 22,246,471
Non-trainable: 0

1) YOLO model benchmarking and selection: YOLOv8 Nano is the most suitable for real-time field surveillance with the fastest inference time, 193.25ms per frame, and the highest FPS, 5.17fps. YOLOv8 Large and YOLOv5 Large have much higher inference times, making them unsuitable for real-time applications. In summary, YOLOv8 Nano provides the closest compromise between accuracy of detection and the speed of the system, and is the ideal choice for the proposed herbivorous animal surveillance framework. As indicated in the below Table VII.

TABLE VII. SELECTED YOLO MODEL METRICS

Model	Pre	Rec	F1-Score	mAP@0.5	mAP@0.5:0.95	Inference Time (ms)	FPS
YOLOv8 Nano	0.8133	0.8159	0.7947	0.5821	0.3198	193.25	5.17
YOLOv8 Large	0.7298	0.7178	0.7144	0.5304	0.2894	2617.14	0.38
YOLOv8 Medium	0.7984	0.7722	0.7723	0.5241	0.2970	861.29	1.16
YOLOv8 Small	0.7917	0.7828	0.7732	0.5724	0.3537	363.09	2.75
YOLOv5 Large	0.7919	0.6683	0.6862	0.4693	0.2679	2574.43	0.39
Yolov5 meduim	0.87142	0.871429	0.861282	0.544692	0.317363	730.0422	1.369784
Yolov5small	0.60094	0.574359	0.501412	0.011558	0.001967	318.9177	3.135605

TABLE VIII. SELECTED MULT-TASK CNN METRICS

Model	Sp.Acc	Sp.Pre	Sp.Rec	Sp.F1	Be.Acc	Be.Pre	Be.Rec	Be.F1	Inference(ms)	FPS
CUSTOMIZECNN	0.9772	0.9775	0.9771	0.9771	0.9814	0.9816	0.9812	0.9814	3.18	314
EFFICIENTNETV1	0.2627	0.1319	0.2498	0.1536	0.4721	0.2361	0.5000	0.3207	6.77	147.7
EFFICIENTNETV2	0.2517	0.2470	0.2457	0.1908	0.5507	0.7050	0.5733	0.4779	2.68	372.7

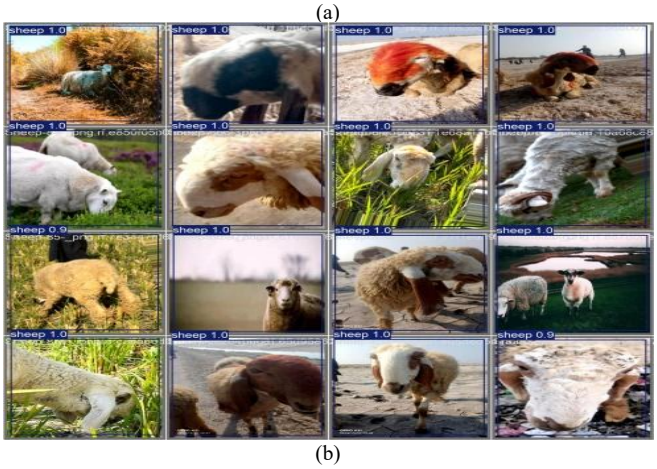
RESNET	0.9975	0.9975	0.9975	0.9975	0.9949	0.9950	0.9948	0.9949	3.30	303.3

The best overall performance was the YOLOv8-Nano model, which was chosen as the backbone of the detection network in RAID-Net.



2) Selected multi-task CNN model results: In the multi-task classification experiment, CNN architectures were tested. Table VIII shows that the customized CNN model has the best inference time and frame per second (FPS). The Customized CNN is determined to be the best classification backbone in RAID-Net.

B. Results and Analysis

The image in Fig. 11 (a) shows sample outputs of an animal detection system where different herbivorous animals are identified using bounding boxes. Each box identifies the presence of animals like camel, cow, goat, sheep, and buffalo in various scenes.

(a)

(b)

Fig. 11. (a) The training images; (b) The validation images.

The image in Fig. 11 shows sample outputs of an animal detection system where different herbivorous animals are identified using bounding boxes. Every box identifies the presence of animals like camel, cow, goat, sheep, and buffalo in various scenes.

1) Accuracy comparisons of all yolo models: Fig. 12 is a grouped bar chart that compares the detection accuracy of different livestock species (buffalo, camel, cow, goat, and sheep) using various models of YOLOv5 and YOLOv8, which have different configurations of model sizes (Nano, Small, Medium, and Large). The visualization shows, in comparison, how strong the feature extraction and object localization are in each architecture. It is worth noting that the YOLOv5 Medium model achieves the best performance for these classes in terms of Precision, Recall, and F1-Score, while the YOLOv8 Nano and Small models are extremely competitive in terms of accuracy while having lower model complexity.

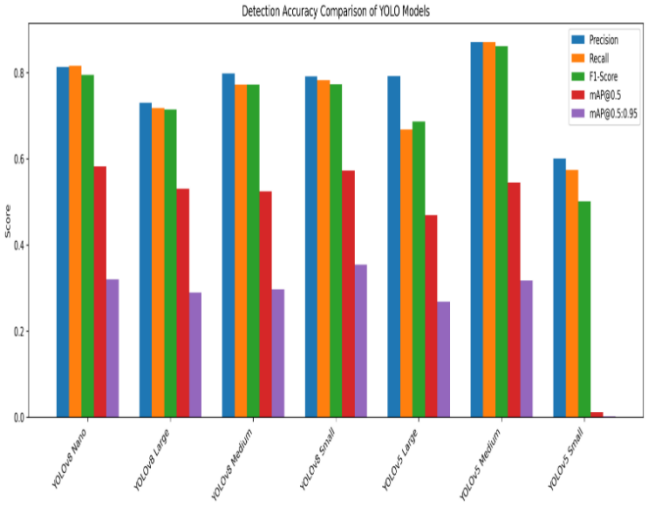


Fig. 12. Detection accuracy comparison.

2) Computational efficiency and speed: Fig. 13 shows the computational efficiency of the tested YOLO models with the help of a dual-axis graph. The primary y-axis (blue bars) represents the inference time for buffalo, camel, cow, goat, and sheep in milliseconds (ms), and the secondary y-axis (the yellow line plot) represents the processing speed (in frames per second: FPS). The figures show clearly that the complexity and the processing speed are inversely related. YOLOv8 Nano not only has the highest FPS and the shortest inference time, but it

also has good deployment potential for live monitoring in the farm.

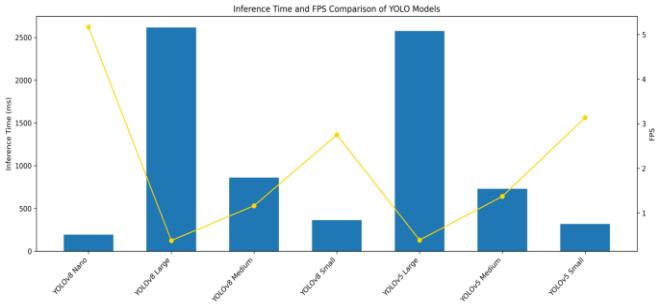

Fig. 13. Computational efficiency and speed.

3) Holistic performance: This radar graph shows a multivariate comparison of the YOLOv5 and YOLOv8 models for buffalo, camel, cow, goat, and sheep detection. The axes range from Precision, Recall, F1-Score, mAP@0.5, mAP@0.5:0.95, Inference_ms, and FPS. The shaded polygons represent the overall performance curve of each model variant, enabling a quick evaluation of the model's detection ability and processing speed. Such a holistic approach is essential to enable the proper selection of the most suitable model architecture that can give high-fidelity identification of objects while maintaining fast inference times required for continuous livestock surveillance. Shown in Fig. 14.

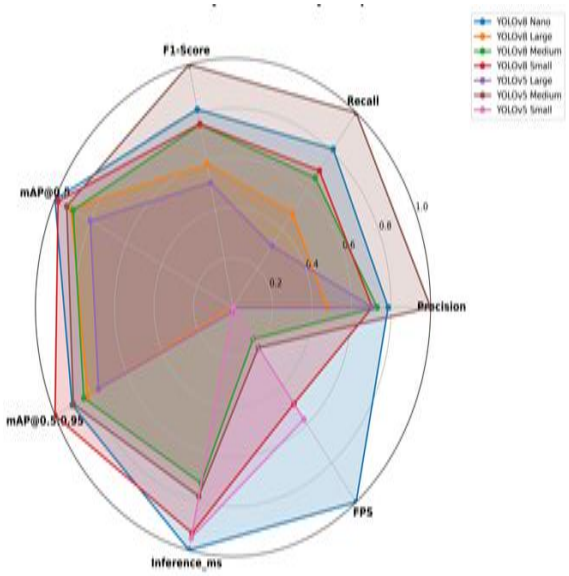

Fig. 14. Holistic performance profiling.

4) CNN model classification performance: These charts demonstrate in Fig. 15 an almost perfect accuracy (close to 1.0) in species and behavior detection of the Custom and ResNet models compared to any of the EfficientNet variants.

5) CNN models inference time and frames per second: This visualization shows that the EfficientNetV2 model has a peak speed of more than 350 FPS, but at the cost of classification accuracy compared to the Custom model, as shown in Fig. 16.

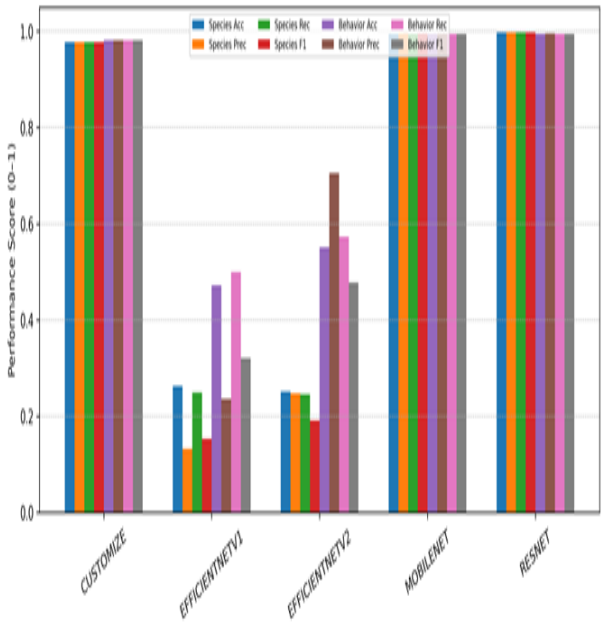

Fig. 15. Classification performance of CNN models.

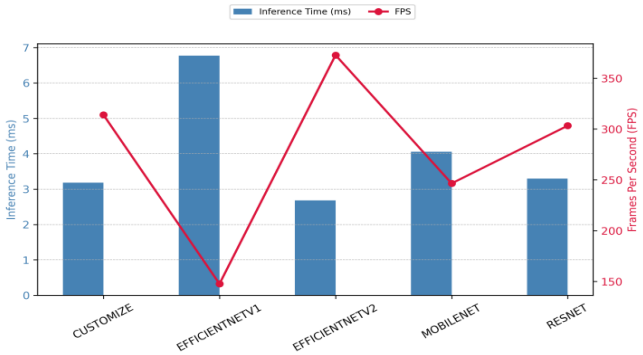

Fig. 16. CNN inference time and FPS.

6) Classification models accuracy and efficiency radar: This summary radar chart demonstrates that overall, the customized models are the most consistent and accurate on all behavior and species metrics. Shown in Fig. 17.

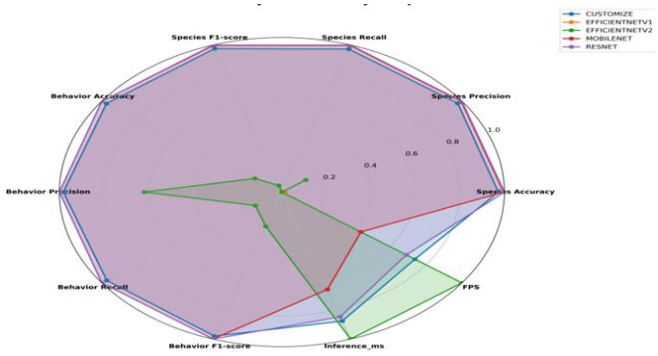

Fig. 17. CNN accuracy and efficiency radar.

7) RAID-Net results: The primary success of the integrated system is compactly summarized in this bar chart: With high Species Accuracy (0.9005) and Behavior Accuracy (0.9431), an

outstanding Alert Precision of 0.9892 is achieved. As shown in Fig. 18, the Customized Multi-task CNN performed 97.72% species classification and 98.14% behaviour recognition accuracy. The complete RAID-Net pipeline, however, has a Hybrid Accuracy of 82.73%, which indicates the overall accuracy of the system at the object detection, ROI localization, classification, and decision-level alert processing stages. Thus, the standalone CNN results are not to be considered the end-to-end accuracy of RAID-Net.

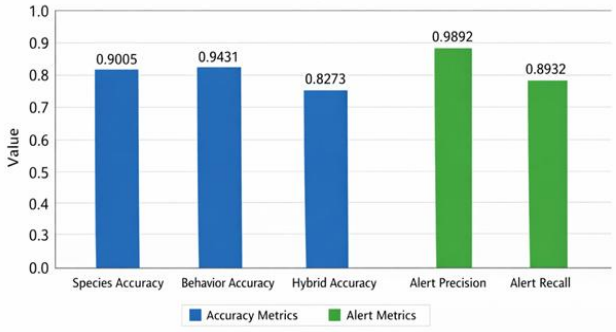

Fig. 18. Performance metrics of the RAID-NET.

Real-time performance is ensured in the system with an average value of 17.61ms and an average FPS of 56.79, suitable for live surveillance applications (Fig. 19).

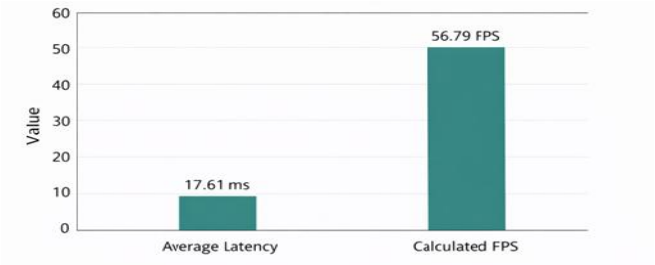

Fig. 19. Latency and FPS performance of the RAID-Net.

This visualization shows the overall performance of your custom framework, showcasing well-balanced high accuracy in hybrid, reliability in alerts, and computational latency.

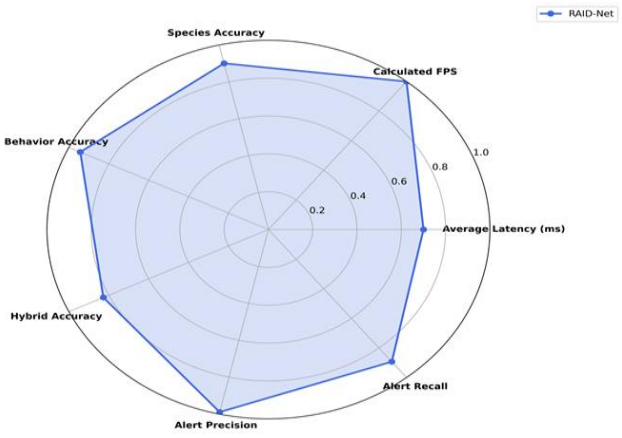

Fig. 20. RAID-Net performance metrics radar chart.

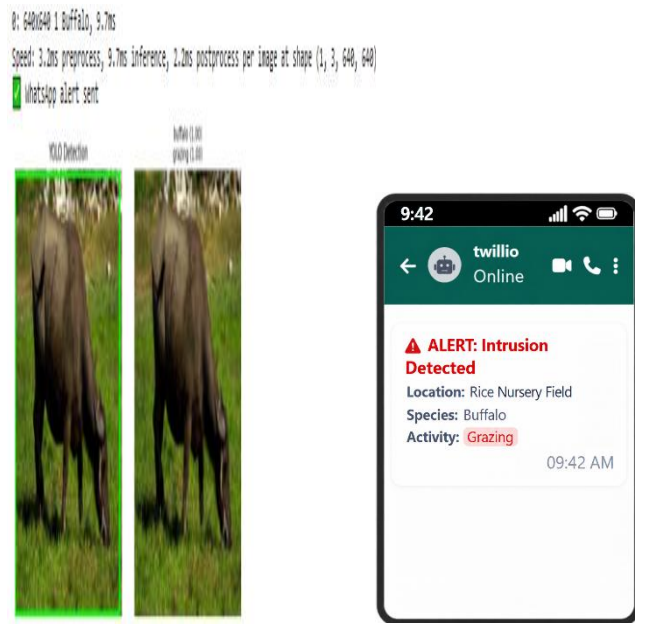
The radar chart shows the overall performance of the RAID-Net model, illustrated in Fig. 20. Species and behavior accuracy are high, and alert precision/recall and computational efficiency are also high.



8) RAID-Net performance: The RAID-Net was tested in terms of performance and its feasibility in agricultural applications. The main performance characteristics of the system are summarized in Table IX. The model's Species Accuracy was found to be 90.05%, showing that it was able to identify herbivorous animals with a high level of accuracy, while the Behavior Accuracy was determined to be 94.31%, demonstrating the model's ability to accurately identify animal behavior. The overall Hybrid Accuracy was found to be 82.73%, as a result of the integration of species and behavior recognition

TABLE IX. PERFORMANCE METRICS OF THE RAID-NET

Metric	Value
Average Latency (ms)	17.61
Calculated FPS	56.79
Species Accuracy	0.9005
Behavior Accuracy	0.9431
Hybrid Accuracy	0.8273
Alert Precision	0.9892
Alert Recall	0.8932

These performance metrics are shown in Fig. 18. The accuracy-related metrics Species, Behavior, and Hybrid are represented in blue, while the alert-related metrics Precision and Recall are represented in green. The high Alert Precision of 98.92% indicates that the majority of alerts that the system issues are valid, while the Alert Recall of 89.32% indicates that the majority of relevant intrusion events are detected. The system can be used for real-time monitoring for suitable live agricultural applications with an average latency of 17.61ms and calculated FPS of 56.79.

9) Experimental evaluation of RAID-Net for grazing detection and moving animal tracking: Real-time detection and automated response mechanisms showcase the end-to-end capabilities of the proposed framework. The system successfully identified buffalo that are grazing with a high confidence score and also calculated the inference speed to achieve low-latency performance, as shown in Fig. 21(a). When such an intrusion is detected, the framework automatically sends an SMS to a mobile device through the Twilio API, sending a precise alert to the farm manager over WhatsApp, indicating the location, type of species, and what was seen on the farm. Moreover, the explanation of how the intrusion detection and audio warning system works is given practically in the rice nursery field in Fig. 21(b). In this case, the model detects a goat intrusion and triggers an audible alarm very quickly, which means an immediate physical deterrent to help prevent the crops from being damaged.

(a)

(b)

Fig. 21. (a) Real-time detection and automated WhatsApp alert, (b) Intrusion detection and audio warning system.

V. Ablation Study

To assess the contribution of each component in the RAID-NET, three different configurations were tested: YOLO only, CNN only, and RAID-Net. The summary of key performance metrics for the RAID-NET model is shown in Table VII. Results show the RAID-Net model is always superior to single-component models, giving the highest FPS with high accuracy in species recognition and behavior recognition. Specifically, the hybrid configuration shows that the integration of the detection system based on YOLO with multi-task CNN classification and severity modelling system achieves the Species Accuracy of 90.05%, Behavior Accuracy of 94.31%, and Hybrid Accuracy of 82.73%, respectively, showing efficient inference and reliable recognition.

VI. Limitation

Although the RAID-NET has great potential, some drawbacks still exist. First, the model has been trained and tested largely with daytime data, which may limit its performance at night. Secondly, the current system has no thermal imaging function that would help in detecting people in low-light or obstructed conditions. Lastly, the system has been assessed only in one field test, and the scalability and robustness of the system in various agricultural settings need to be proven. Future studies are needed to address these limitations to improve the versatility and reliability of the model for use in practical farming.

VII. Future Work

These are just some of the future enhancements that are planned for the RAID-NET, and they will help the system become more accurate, scalable, and adaptable. In conclusion, the RAID-NET is a promising solution that has the potential to revolutionize agricultural monitoring in the future. The creation of a vision of the environment and an assessment of the thresholds for confidence. Environmental visual-condition analysis and assessment of thresholds of confidence.

VIII. Conclusion

In this study, the hybrid deep learning-based real-time, behavior-aware herbivorous animal intrusion detection system in rice nursery fields, called RAID-Net, is proposed. The system can detect a variety of species and distinguish their actions by using YOLO-based detection, multi-task CNN classification, and severity modeling, which have high detection accuracy and can effectively reduce false alarms. The outcomes show that RAID-Net is a promising tool to improve the efficiency of agricultural surveillance, giving earlier alerts for crop protection, and reducing labour costs. Moreover, it is an extensible and edge-deployment-friendly framework and offers a smart and feasible protection solution for modern agriculture. Overall, RAID-Net is a strong artificial intelligence-based solution to protect rice nursery fields from herbivorous intrusion, which will help achieve sustainable and technology-driven agriculture.

Interpretable Deep Convolutional Neural Network Framework for Online Reputation Management Using Customer Reviews and Social Media Feedback

An Interpretable Deep Learning Approach for Online Reputation Management

Faculty of Computer Studies, Arab Open University, Riyadh, Saudi Arabia[1, 2]
Faculty of Computing and Information Technology, King Abdulaziz University, Jeddah, Saudi Arabia[3]

***Abstract*—Social media has become a significant channel for communication and interaction, significantly influencing how organizations are perceived in the digital era. Online reputation management (ORM), as an addition to public relations, concentrates on shaping and maintaining an organization's image through continuous surveillance of customer reviews and online feedback. Traditional methodologies, such as machine learning and deep learning–based reputation management, depend upon learned patterns and predetermined features from historical information; recent ORM approaches exploit real-world data from social platforms to extract dynamic public sentiment. Meanwhile, online opinions can transform rapidly because of human-generated text, and preserving a reliable reputation has become progressively difficult for organizations. To improve interpretability and transparency, explainable AI algorithms are frequently incorporated into recent ORM architectures. This study presents an Interpretable Deep Convolutional Neural Network Framework for Online Reputation Management (IDCNN-ORM). The proposed model integrates an improved mRMR approach to identify highly informative and non-redundant features. Moreover, the deep convolutional neural network is applied to learn hierarchical feature representations from input data. The Adabelief optimizer is integrated into the proposed framework to enhance training stability by adaptively refining the learning process. Furthermore, the LIME-based explainability artificial intelligence technique is utilized to enhance transparency in the model's decision-making process. The experimental analysis of the proposed IDCNN-ORM model is carried out using the Social Media Sentiments Analysis Dataset. The comparative analysis demonstrates promising performance with an accuracy of 94.85% compared with existing methodologies.**

***Keywords*—Online reputation management; social media feedback; adabelief optimizer; explainable artificial intelligence; deep convolutional neural network**

I. Introduction

Social media networks have developed into an important platform where customers can express their sentiments, engage with brands, and share their experiences in the modern world [1]. The velocity and volume of user-generated content (UGC) on applications like LinkedIn, Facebook, YouTube, Twitter, and Instagram offer a valuable data resource that can be used for several marketing purposes.

*Corresponding author.

Among these, Online reputation management (ORM) is the process of improving, tracking, observing, and handling an individual's or organization's reputation in the digital era [2]. Nowadays, UGC plays an essential part in influencing public perception through blog comments, feedback, ratings, posts, forums, and reviews. Although UGC has enhanced data sources, it is difficult to extract useful and meaningful insights from the volume and the considerable difficulty [3]. Reading and analyzing the sentiment of all relevant online texts requires huge effort and time, and it is frequently quite subjective. Experts struggle with a huge amount of information, unreliable language, and complex emotional interpretation [4]. This type of interpretation is ineffective and restricts a firm's capability to gather real-world insights, respond quickly to novel issues, and evaluate opinions through large-scale databases or prolonged periods. Inefficient processing of data streams can result in a failure to understand consumer requirements, enhance promotional measures, and prevent damage to brand reputation [5].

Over the past few decades, sentiment analysis (SA) has evolved as a vital domain within machine learning (ML) and natural language processing (NLP), driven by the explosive growth of digital information [6]. Given the applications of social media networks, customer opinion, online reviews, and feedback, comprehending the sentiments extracted in a text is important [7]. SA, termed opinion mining, is the computing operation of classifying, mining, and evaluating subjective data from a text or content to determine the complete attitude or sentiment expressed toward specific products, entities, events, or topics [8]. This method includes identifying text into pre-defined classes like neutral, positive, and negative sentiments, or more refined opinions and emotions. Usually, ML-driven SA methods are extended, and novel gaps are classified by SA identification. There is a move toward using more intricate methods to solve this limitation [9]. Deep learning (DL) models are a branch of the ML framework that provide effective solutions to these tasks with structures that involve recurrent neural networks (RNNs) and Long Short-Term Memory (LSTM), indicating efficiency in managing intricate SA challenges. These methods have gained attention for their capability of capturing the contextual interaction within text and have exhibited better performance compared with other DL models in sentiment analysis tasks [10].

Online Reputation Management (ORM) has become important owing to the huge increase in social media feedback and customer comments on digital platforms. Organizations need an automatic strategy to examine a huge amount of noisy and unstructured textual data in the real world. The Kaggle social media sentiment analysis dataset signifies real-time sentiment demonstrations from distinct online sources. Conventional ML systems frequently fail to extract semantic relationships and deep contextual information in certain cases. Therefore, there is a need for innovative DL-based techniques to enhance feature representation and sentiment classifier outcomes in ORM models. This motivates the proposed Interpretable Deep Convolutional Neural Network Framework for Online Reputation Management (IDCNN-ORM) using social media data.

- Utilize an improved mRMR approach to effectively select the most relevant and non-redundant features from the dataset.
- Design a deep convolutional neural network (DCNN) approach to learn hierarchical feature representations from input data by continuously capturing complex patterns at multiple levels to improve classification performance.
- Present an Adabelief optimizer for adaptively modifying learning rates, thereby ensuring stable and efficient training.
- Integrate a LIME-based explainable artificial intelligence (XAI) model for providing interpretability and improving transparency in the decision-making process.
- Evaluate the performance of the proposed model using the Social Media Sentiments Analysis Dataset, demonstrating its effectiveness under various evaluation measures.

II. Literature Review

This section concisely reviews the existing research on online reputation management. Semenda et al. [11] discussed the objective of matrix-based examination and game theory in improving social media marketing algorithms for e-commerce industries. To integrate these mathematical techniques with social media analytics, the goal is to deliver a comprehensive architecture that can predict customer action. This system allows sellers to organize more adaptive, targeted, and efficient marketing campaigns, drive growth, and improve customer fulfillment in the digital marketplace. Istanbulluoglu and Sakman [12] examined the associations among business responses to customer repurchase intentions and social media complaints. The connection between purchase intention and the five scopes of handling complaints, as led by customer trust in the corporation, was surveyed, and users' propensity to trust was hypothesized as a mediator in this correlation. Saheb et al. [13] examined the connection between social media and AI. The study employs a mixed-model strategy to examine 1540 scholar records, incorporating systematic literature review and bibliometric approaches. The major objective of this study is to detect the most significant themes and trends, and also the impact of company values and suggestions, in the AI Social Media field. The initial level of the study encompassed a quantitative keyword analysis, which led to the identification of ten key themes.

Alsemaree et al. [14] offer the requirement for a nuanced consideration of consumer sentiments under several coffee goods, allowing corporations to generate informed decisions concerning improvement, discontinuation, and product promotion. Antczak [15] discusses the major goals for exploring the connections among social media marketing, digital marketing, and customers' online purchasing actions. The study will investigate how marketing actions in social media and digital media, namely social media advertising, product reviews, influencer marketing, and e-mail marketing, impact user behavior and purchase choices. The authors [16] proposed a systematic literature review (SLR) investigating the role of SMIs in the e-commerce market. This study examines recent knowledge on how influencer authority, demarcated by expertise, trustworthiness, and reliability, impacts user behavior, purchase intention, and brand engagement. Odionu et al. [17] introduced the use of big data analytics for enhancing CRM engagement and retention approaches. The main goal is to examine how big data analytics can be exploited to gain insights into consumer actions, interactions, and preferences, thus enhancing CRM proposals. This study contains a comprehensive literature review and case study examination of organizations that have effectively incorporated big data analytics into their CRM methodology.

Existing sentiment analysis systems for ORM are frequently limited in interpretability, making their forecasting complex to trust in real applications. Several strategies fail to efficiently manage noisy and informal social media content, namely, emojis, abbreviations, and slang. The usage of CNN-based frameworks to capture hierarchical textual attributes is still unexplored in comparison with DL algorithms. Furthermore, more research focuses on accuracy without combining explainability methodologies. There is a limited number of unique architecture that integrates higher results with method transparency.

III. Methodological Framework
